## Ion exchangers from Pharmacia Fine Chemicals

The better choice because ion exchangers from Pharmacia Fine Chemicals have excellent capacities, do not have to be decanted, and require the minimum of preparation.

Better results because ion exchangers from Pharmacia Fine Chemicals are bead formed, making them easy to pack and quick to run. Separations can be repeated many times in the same column.

Better information can be found in the NEW handbook "Ion exchange principles and methods" and the Literature Reference Lists, available free on request from Pharmacia Fine Chemicals.

# Incubator for Tissue Cultures

Heraeus CO<sub>2</sub>-Incubator BL 5060 EK/CO<sub>2</sub>

We build the incubator with appropriate pCO<sub>2</sub>, pH and pO<sub>2</sub> control units.

It is Heraeus that produce incubators incorporating means for control of the pCO<sub>2</sub>, pH, pO<sub>2</sub>, pN<sub>2</sub> and rH, as well as for hot air sterilization.

In the intact living organism, the pCO<sub>2</sub>, pO<sub>2</sub> and pH of the cell environment are in a state of biochemical and physiological equilibrium.

In the Heraeus Incubators for Tissue Cultures, all environmental parameters are ideally matched to the natural environmental conditions of the cells.

When Petriperm<sup>®</sup> Tissue Culture Dishes are used, gradients of the pCO<sub>2</sub>, pO<sub>2</sub> and pH are avoided in the micro-environment of monolayer cell cultures.

## Petriperm<sup>®</sup>

a novel culture dish with gas permeable membrane as cellular support

Additional advantages of the Petriperm<sup>®</sup> membrane are:

- UV permeable 200 nm
- Suitable for high power light and fluorescence microscopy
- The membrane can be cut for cell cloning, electron microscopy, staining and documentation.
- Chemically resistant to acids, bases and organic solvents.

### Survival in the Wild

Each species of wild animal or plant, beset by a unique series of problems, has evolved its own array of strategies to enable it to survive. The living world, therefore, displays an almost bewildering diversity of these strategies, which this new series aims to describe. The first three books in the series have just been published and they are: *Feeding Strategy* by Jennifer Owen, *Camouflage and Mimicry* by Denis Owen, and *Sexual Strategy* by Tim Halliday. Each book is beautifully illustrated, and includes 32 pages of colour photographs. Illustrated £6.95 each

### Complementary Variational Principles

New edition

A.M. Arthurs

In this book the solution of boundary value problems for linear and nonlinear partial differential equations arising in mathematical physics, chemistry, engineering, and biology is presented for graduate students and for engineers and scientists. There are thirty examples from these fields. This edition is completely revised and enlarged to include many results and new derivations. Second edition £16 Oxford Mathematical Monographs

### The Development of the Vertebrate Limb

An Approach through Experiment, Genetics, and Evolution

J.R. Hinchliffe and D.R. Johnson

Starting with a sketch of the evolutionary history of the pentadactyl limb, the authors describe and analyse the processes of limb development, first at the level of tissue interaction and then at the level of pattern formation. The ectoderm-mesoderm dialogue is approached through the classic grafting experiments on reassembled chick limb buds. Positional-information approaches to pattern formation propose the zone of polarizing activity as a source of an anterior-posterior gradient and a clock-face model to explain amphibian limb regeneration. An account is given of attempts at computer simulation of limb pattern, and the authors conclude with a discussion of the genetic mechanisms controlling limb development. Illustrated £20

*Handwritten:* R513 R41A

### The Mathematical Theory of Quantitative Genetics

M.G. Bulmer

The emphasis in this book is on discussion of the underlying principles illustrated by simple examples. A basic knowledge of statistical methods and theory is assumed and problems for solution are included. £27

## GUIDE TO AUTHORS

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

**Manuscripts** may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible:  $\exp(a)$  is preferred to  $e^a$  if 'a' is more than one character.

**References** are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

**Artwork** should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

*Nature's* publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

## New Titles from G+B

### A Perspective of Physics, Vol. 4

Selections from 1979 Comments on  
Modern Physics

Edited by Sir Harrie Massey

The latest volume in the annual serial designed to give an overview of the various fields in modern physics and to keep both the specialist reader and the interested observer abreast of current developments.

December 1980 360 pp 0 677 16190 5 US \$35.50

### Solar Flare Magnetohydrodynamics

Edited by E. R. Priest

Tremendous advances in the observations of solar flares have taken place in recent years, both from high-resolution ground-based instruments and space telescopes such as those on board Skylab and Solar Maximum Mission satellites. This book presents descriptions of previous work together with more recent unpublished calculations.

December 1980 approx 560 pp 0 677 05530 7 In prep.

### Plasma Astrophysics:

Nonthermal Processes in Diffuse Magnetized  
Plasmas

Vol. 1: The Emission, Absorption and Transfer  
of Waves in Plasmas

Vol. 2: Astrophysical Applications

D. B. Melrose

Written primarily for graduate students in plasma astrophysics and for astrophysicists and geophysicists who wish to learn relevant plasma physics. In Volume 1 plasma theory is developed in a systematic way from first principles, and Volume 2 presents the astrophysical applications and source of the more advanced plasma theory.

Volume 1: 290 pp 0 677 02340 5 US \$46.00

Volume 2: 434 pp 0 677 02130 5 US \$64.50

2-vol. set 0 677 03490 3 US \$99.50

July 1980

### A Theoretical Approach to the Preselection of Carcinogens and Chemical Carcinogenesis

Veljo Veljkovic

Presents a simple valence theory of carcinogenesis, using a new approach to quantitative treatment of molecular biology and chemical carcinogenesis problems. A new, quick test for prediction of carcinogenicity of chemical substances is given together with guidance for selection, design and use in therapy of antitumor agents, antibiotics, psychopharmaceuticals and other medical drugs within the framework of valence theory.

November 1980 125 pp 0 677 05490 4 approx US \$25.00

### Physics of the Paranormal

Edited by John Taylor

This book is an attempt to bring the knowledge and critical approach of modern science to bear on supernatural phenomena. Whilst such an approach is not new, this work is almost unique in containing contributions by a group of scientists on their investigations into various paranormal events, and thus the scientific approach is firmly followed in all articles.

October 1980 402 pp 0 677 16170 0 US \$19.50

# Spiders

E.O. Wilson: Let me remind you that people everywhere, a large percent of the population, at a very early age have already developed a deep horror at the sight of snakes or spiders with nothing more than gentle nudging from their parents, if that. Yet, in spite of the fact that parents constantly reinforce their children against going near electric sockets, automobiles, knives and the like, phobias against such objects rarely develop.

Marvin Harris: Let's go back again to the possibility that these phobias are genetically programmed — which I'm willing to grant. The overwhelming bulk of the socially conditioned response repertoires of different human societies consists, by your own admission, of culturally determined rather than genetically determined traits. Then it seems to me that when one offers a cogent culturological explanation of these phobias, it has to be considered that this explanation is not offered in isolation.

from a debate between E.O. Wilson and Marvin Harris in sociobiology. In *The Sciences*. From family constellations to galaxies, *The Sciences* takes the critical look. Handsome, original, lively, *The Sciences* represents the best science commentary you'll find anywhere on human behavior, culture, the physical sciences — by Ashley Montagu, Stephen Jay Gould, B.F. Skinner, Napoleon Chagnon, Peter Medawar. ... Subscribe today. It's only \$12.50 a year.

*The Sciences*. More than science.

☐ Here's my check or money order for \$12.50 (\$2.50 off the newsstand price) for the next ten issues of *The Sciences*.  
Foreign individuals add \$5.00  
Foreign institutions add \$10.00  
US institutions add \$5.00

**CALL FOR PAPERS:** Manuscripts on the synthesis of biologically and medically relevant proteins, genomic organization, chromosomal gene mapping, gene structure, regulation of gene expression, molecular and biochemical studies on genetic diseases, and plant molecular biology are invited for submission. Publication will begin early in 1981. To avoid excessive reduction, the journal will provide generous space for inclusion of figures. The most modern computer typesetting techniques will facilitate rapid publication. The publisher will be Raven Press, New York. Submit manuscripts in triplicate to the Editor-in-Chief at the above address. References should be cited by number in the text and numbered in order of citation; provide complete titles of articles cited, with names of all authors and inclusive pagination. Full instructions to contributors are available from the Editor-in-Chief or from Raven Press.

Circle No. 04 on Reader Enquiry Card.

## SUBSCRIPTION ORDER FORM

TO: **RAVEN PRESS 1140 Avenue of the Americas, New York, N.Y. 10036, U.S.A.** Date \_\_\_\_\_

Please enter my subscription for Volume 1 (1981) of **JOURNAL OF MOLECULAR AND APPLIED GENETICS**.

Published bimonthly. **Personal subscription rates:** U.S. \$80; elsewhere \$90.

**Institutional subscription rates:** U.S. \$135; elsewhere \$145.

Air delivery is *included* for European and Mediterranean countries;  
for air service *elsewhere* add \$15.00.

Name (please print) \_\_\_\_\_

## Immunochemicals from Amersham

New, exclusive

**Anti-mouse Fab from rabbit,  $^{125}\text{I}$ -labelled,  $\text{F(ab')}_2$  fragment** IM.113

- ★ For the assay of cell-surface and soluble antigens and hybridoma screening
- ★ Recognizes Fab portion of all classes and subclasses of mouse IgG
- ★ Does not bind to heavy chain Fc fragments
- ★ Specific activity of  $10\text{--}50\mu\text{Ci}/\mu\text{g}$  for optimum binding capacity
- ★ Purified by affinity chromatography and gel filtration
- ★ Biologically tested for binding ability to immobilized mouse IgG

Already available

**Protein A,  $^{125}\text{I}$ -labelled with Bolton and Hunter reagent** IM.112

**Protein A, *N*-[propionyl- $^3\text{H}$ ]propionylated** TRK.653

- ★ For the quantitative assay of cell-surface and soluble antigens
- ★ Binds to Fc portions of many classes and subclasses of immunoglobulins
- ★ Biologically tested for binding ability to immobilized mouse IgG

## A new Multipurpose Cell-Test-Chamber-System\* (Pentz-Kammer)

TCSC-1\*

standard

with PTFE-adaptor

### General application

- Cell cultivation in one to ten areas (variable in height and volume) on slides, cover slips or plastic foils.
- Analysis of human, animal and plant tissue and microorganisms.
- Pharmatests, Immunofluorescence, Autoradiography etc.
- Perfusion chamber.
- For still and motion photography.
- The sterilizable chambers ( $+165^\circ\text{C}$ ) enables experiments with infectious bacterial and viral material.

for electrone microscopic investigations

### Additional accessories

- Different silicone gaskets and PTFE-inserts for numerous inquirments.
- Gas ring ● gas cassette ● heating and gas frame
- heatable work-plate ● temperature control unit

For more information please contact:

**BACHOFER GmbH, P.O. Box 7089,  
D-7410 Reutlingen, FRG (W-Germany), or by  
LEITZ representative (Optical Division).**

standard

with PTFE-insert  
with 10 wells

### Erratum

Due to an error in the *Nature* office, an incompletely revised version of the paper "Anomalous region on Mars: implications for near-surface liquid water" by S. H. Zisk and P. J. Mougins-Mark was published in the issue of 13 November (288, 126-129, 1980). The authors' corrections will appear shortly in an appropriate form.

## Less is more.

Less Work.  
More Dependability.

They're ready-to-use kits with everything you need except your sample. Room temperature set-up, no salting out, no second incubation. We've pre-reacted the first antibody with the second antibody to save you time.

And we've given you NEN quality to assure you of dependable assays — accurate and reproducible. Sensitivity reaches the femtomole range with the acetylating reagents provided. A tritium-labeled marker is included to monitor recovery. The iodinated tracer is exceptionally stable.

These are some of the reasons to choose NEN's Cyclic AMP and GMP [ $^{125}\text{I}$ ] RIA kits, the world's most widely used for their convenience and quality. Send for the whole story in our technical brochure.

Not for use in humans or clinical diagnosis.

# The Cell Sorters.

## Affinity chromatography is the simplest technique for purifying many macromolecules – now you can use this method for separating cells too!

Affinity chromatography is the simple, rapid technique that separates cell subpopulations according to their unique surface properties. You can separate more than  $10^8$  cells in under 3 hours using only 2–5 ml of affinity adsorbent. The same adsorbent can be used many times, giving you economical and reproducible separations. Choose the adsorbent you need from our range of affinity gels made from Sepharose® 6MB – the gel developed specially for cell separation.

**New!**

**Protein A-Sepharose 6MB**

a versatile new adsorbent for use together with specific antibodies for separating many types of cells

**Helix pomatia Lectin-Sepharose 6MB**

separates T and B cells for immunological studies and tissue typing

**Wheat germ Lectin-Sepharose 6MB**

for subfractionating lymphocytes and other cells

**CNBr-activated Sepharose 6MB**

ready-activated Macrobeads that make it easy to prepare your own adsorbents for cell separation

**Contact us today for your own free copy of our new booklet:  
"Cell affinity chromatography – principles and methods".**

# Getting down to the finer details of microelectronics

As a leading manufacturer, and user, of micro-electronic technology, Philips is constantly searching for techniques that will improve the production process, or the product, or – ideally – both. This objective has now been achieved with the development of the 'Beamwriter' vector scan lithography system. In fact, it's the only production-oriented vector scan electron beam writing system available in the world.

Compared to conventional optical lithography techniques, vector scanning produces significant savings in the time taken to produce a set of masks or reticles; hours instead of days. It is also much more efficient than the raster scan E-beam method because the writing beam is directed only to points where exposure is required. The Beamwriter also generates an exposure dosage twenty times greater than other

# Contributions to Cell Science

## FIBRONECTINS

Bethesda Research Laboratories, Inc. is now the source for cell culture growth and regulatory factors. Continuing the tradition of BRL excellence, tissue culture reagents from our Biological Chemistry Laboratory meet the most challenging and rigorous standards of purity and performance. As illustrated below, the electrophoretic homogeneity of BRL Fibronectin (>98%) is far superior to that from other suppliers (Figure 1). Similarly, the murine thymocyte proliferation assay (Figure 2) establishes that our Interleukin-2 (IL-2) is *lectin-free*, the critical factor for selection and long-term maintenance of monospecific T-cell clones.

**Figure 1**

### Electrophoretic and Total Protein Analyses of Fibronectins

To analyze the homogeneity and relative protein content of human plasma fibronectin from BRL and two other commercial sources, 1 milligram vials from each supplier were reconstituted to a volume of 1 milliliter.

Aliquots from each source were then subjected to SDS-polyacrylamide gel electrophoresis and total protein determination.

## INTERLEUKIN - 2

Mouse thymocytes incorporate [<sup>3</sup>H]-thymidine in response to phytohemagglutinin (PHA) and IL-2 stimulation, but will not proliferate (and incorporate [<sup>3</sup>H]-thymidine) following stimulation with IL-2 alone. To assay for PHA-dependent stimulation, 200 µl cultures of murine thymocytes (2 x 10<sup>6</sup> cells/ml) were incubated at 37 °C for 68 hours in the presence of the test medium; pulsed with 0.5 µCi [<sup>3</sup>H]-thymidine for 4 hours, then assayed for incorporation of the radiolabel.

Thyroglobulin-agarose (T-A) chromatography is used to remove lectins from mouse lymphoma-conditioned medium (source of BRL mouse IL-2). Mouse lymphocyte proliferation was measured under each of the following conditions: Stimulus A, Normal culture medium; Stimulus B, Normal culture medium +1% PHA; Stimulus C, Normal culture medium +1% PHA and 312 units IL-2; Stimulus D, Normal culture medium +1% PHA and 326 units IL-2 after one cycle T-A chromatography; Stimulus E, Normal culture medium +1% PHA and 376 units IL-2 after two cycles\* of T-A chromatography.

\*Standard BRL production method

**Figure 2**

### Murine Lymphocyte Proliferation Assay for Lectin Removal from BRL IL-2 Before and After Thyroglobulin-Agarose Chromatography.

## Soon to be available. . .

- Human Cellular and Chick Cellular Fibronectins
- Epidermal Growth Factor

Watch for further data on the unmatched purity and performance of Human plasma fibronectin and Interleukin-2 from the Biological Chemistry Laboratory of BRL.

**CALL FOR PAPERS:** Manuscripts on the synthesis of biologically and medically relevant proteins, genomic organization, chromosomal gene mapping, gene structure, regulation of gene expression, molecular and biochemical studies on genetic diseases, and plant molecular biology are invited for submission. Publication will begin early in 1981. To avoid excessive reduction, the journal will provide generous space for inclusion of figures. The most modern computer typesetting techniques will facilitate rapid publication. The publisher will be Raven Press, New York. Submit manuscripts in triplicate to the Editor-in-Chief at the above address. References should be cited by number in the text and numbered in order of citation; provide complete titles of articles cited, with names of all authors and inclusive pagination. Full instructions to contributors are available from the Editor-in-Chief or from Raven Press.

Circle No.29 on Reader Enquiry Card.

## SUBSCRIPTION ORDER FORM

TO: **RAVEN PRESS 1140 Avenue of the Americas, New York, N.Y. 10036, U.S.A.** Date \_\_\_\_\_

Please enter my subscription for Volume 1 (1981) of **JOURNAL OF MOLECULAR AND APPLIED GENETICS**.

Published bimonthly. **Personal subscription rates:** U.S. \$80; elsewhere \$90.

**Institutional subscription rates:** U.S. \$135; elsewhere \$145.

Air delivery is included for European and Mediterranean countries;  
for air service elsewhere add \$15.00.

## MISCELLANY

PEARCE LIBRARY  
 SCIENCE COLLEGE  
 3000 GLENVIEW ROAD  
 CHICAGO, ILL. 60637

# THE USE OF CHEMICAL NOMENCLATURE.

**An important symposium.**

**To be held at Church House, Great Smith Street,  
Westminster, London S.W.1., 24th-26th March, 1981.**

**28 internationally known speakers will cover the following subjects:-**

- \* Problems of the day to day use and misuse of chemical nomenclature.
- \* Standardisation.
- \* Industry/Sector problems.
- \* Sources of help.
- \* The use of trivial names, common names, synonyms, trade names and trade marks.
- \* Legal implications.
- \* The use of chemical nomenclature in chemical abstracts.
- \* The problem of translating from English.
- \* Available systems of structure representation.
- \* The problems of using chemical nomenclature to develop an information base.
- \* Problems in the field of biochemical nomenclature.
- \* The need for more effective training.
- \* Symbols and nomenclature as an aid to health and safety.
- \* Harmonisation of nomenclature systems.
- \* Nomenclature - the way ahead.

**Organised by the Laboratory of the Government Chemist in association with the British Crop Protection Council, British Pharmacopoeia Commission, the British Standards Institution, the Chemical Industries Association, the Chemical Notation Association (UK), the Pharmaceutical Society of Great Britain, the United Kingdom Chemical Information Service and the Joint Nomenclature Panel of the Royal Society and Royal Society of Chemistry.**

This three day symposium is designed to help overcome confusion and misunderstandings that exist on the subject of chemical nomenclature.

An internationally known list of speakers will provide a forum in which scientists, educationalists and industrialists can discuss the many problems, as well as learn the latest trends, sources of help and new developments on this subject.

Organised by the Laboratory of the Government Chemist in association with a number of other major organisations, this symposium will create greater understanding of chemical nomenclature in international trade, in the purchase and use of chemicals and in the interpretation of scientific papers.

Inclusive price £69.00. Student reductions and single day rates are available on request.

For full information regarding this symposium, please complete and return the coupon.

To the Symposium Organiser, Laboratory of the Government Chemist, Room 564A, Cornwall House, Stamford Street, London SE1 9NQ.  
Telephone: 01-928 7900, extension 520 or 537.

Please send me full details of the Symposium, 'The Use of Chemical Nomenclature.'

# What are the research councils for?

This week will be a testing time for the research councils which are one of the principal means of support for British scientific research. Both the Medical and Science Research Councils are due to publish their annual reports. Hard on the heels of the annual report of the Natural Environment Research Council (see *Nature* 28 October) these documents will between them provide an opportunity for telling where the research councils collectively are heading. Naturally, readers of these annual reports will have to be prepared to read between the lines. Such reports begin with a more or less ritual recitation of honours bestowed on members of the staff and of visits by members of the royal family to council establishments. These days, there usually follows an account of the difficulties of living within a budget which, if not actually shrinking in real terms, is no longer growing. Occasionally, a council may be so moved by some particular consequence of straitened budgets that it will specifically draw attention to the collapse of some special project. This was the spirit in which the Natural Environment Research Council last week let it be known that the Geological Survey of Britain is now jeopardized by the unwillingness of the Department of the Environment to contribute to its continuing cost. Usually, however, the councils tell their tale with as little commotion as they can.

This year things could — or should — be different. No amount of built-in gentility can conceal from the councils themselves the increasing difficulty of sharing out the funds that come their way from the Department of Education and Science in ways that are likely to be both equitable (as between deserving claimants) and effective (in promoting research of high quality and promise). The collapse of the dual-support system is another problem. If the University Grants Committee can no longer ensure that university departments are well-equipped to conduct research, the research councils must either break with their present practice of not financing basic facilities (which means making fewer grants) or must acknowledge that much of what they spend will be used with less than full effectiveness. The trouble is that there is very little that research councils acting individually can do to shape a more rational pattern for academic research. So long as they stick (as they should) to the principle that grants go to the best applicants, they are bound to find themselves spreading their resources more thinly than is reasonable. This recognition is no doubt part of the reason why the Advisory Board for the Research Councils has set up (with the Committee of Vice-Chancellors and Principals, representing the university sector) the Merrison Committee. The hope is that the committee will be able to evolve a framework within which the old goals of concentrating academic research on selected universities (or university departments) can be made acceptable. It remains to be seen whether the University Grants Committee has the stomach for implementing whatever policy may emerge — and whether the universities will allow it to do so.

The research councils will also be perplexed this year by signs of the possible collapse of the Rothschild system with which they have been living since 1971. So they should be. One among them, the Medical Research Council, has been able to claw back from the Department of Health the now inflated funds taken away progressively in the years after 1973 (see *Nature* 23 October).

Others will be tempted to follow suit, and will earn a dusty answer from the government departments concerned. Sir Hermann Bondi, the new chairman of the Natural Environment Research Council, says that he supports the notion that government departments should act as customers for research (see page 5).

Will he be of the same opinion when he discovers how vulnerable his new council is to inconstancy or even downright fickleness on the part of sponsoring ministries?

The trouble with customers is that they are often wrong, but that their actions inevitably create the illusion that they are right. The decision by the Department of the Environment to cut back its contributions to the British Geological Survey can have one of two consequences. Either the survey will be supported by other means (in which case the department will congratulate itself on having saved some money) or it will be stopped; the United Kingdom will not on that account collapse and the department will take pride in having helped bring an apparently worthless activity to an end. Either way, the customer will seem right. Nobody will have made a serious examination of the value of the Geological Survey.

Taken together, these developments are likely to provoke further soul-searching among the research councils and their sponsors. For the Medical Research Council, the most immediate question is whether it can turn from its largely academic ways so as to earn the £12 million a year it will now have to spend on applied medical research. For all of them, the long-term question is how their functions are to be defined and carried out. During the past Rothschild decade, their relative budgets have hardly changed. Each year, one or two of the councils have had an extra one or two per cent in real terms to spend, while the others have fallen back. But is there any reason to suppose that the sums being spent on research in agriculture, medicine and the natural environment in 1970 are still appropriate a decade later? And is it right that the budget of the Science Research Council, exempted from the rigours of Rothschild, should stand in exactly the same relationship with those of what would be called, in the United States, the "mission-oriented" councils? Can it serve either the interests of research or of the public purse that these increasingly elaborate organizations should just grow, like Topsy?

This is why there is emerging an urgent need for yet another review of what the research councils are for. Although it would be convenient that the review should wait until the Merrison inquiry is completed, that is largely a recipe for postponing until tomorrow what should be undertaken right away. The agenda for an inquiry is, after all, easily conceived. Indeed, the final report of such an inquiry should not unduly tax the imagination.

The research councils have two quite different functions, which collectively they must keep. Two of them were set up to sponsor basic research relevant to the practice of agriculture and medicine. A third, the Natural Environment Research Council, is historically an exercise in wish-fulfilment — it was set up in the early 1960s in the hope that it could put flesh on the bones of the then nascent belief that problems of the environment and natural resources would dominate the remainder of the century. The belief has been justified, but the council has turned out to be a manager of a miscellaneous collection of disparate enterprises. (Presumably part of the reason for putting the organization in the hands of Sir Hermann Bondi is that he may be able to weld them into a more coherent whole; but he will have his work cut out.) Almost incidentally, these three research councils help to foster academic research, partly through research grants to academics, partly by links between their research institutes and neighbouring universities. Both kinds of links are valuable, and should be preserved at all costs.

Change is needed elsewhere, and in particular in the definition of the practical functions of the councils with a mission. In medicine, can it make sense that the Medical Research Council

should take back responsibility for the Rothschild money but still stand only on the sidelines in the support of teaching hospitals and the administration of research within the National Health Service? In agriculture, there is also a case for asking that the old boundary between "basic" and "applied" research should be made more flexible. British agriculture has been uncommonly successful in the past few decades. It might have been even more

successful if the customers and the contractors had lived more in each others' pockets. In short, if the Rothschild recipe is now to be eroded, there are the strongest reasons why the balance should be tilted the other way and the research councils given even more practical marching orders than in the recent past. If, at the same time, they can keep their links with the universities, everybody will be the beneficiary.

## Ideological trouble ahead for Unesco

The United Nations Educational, Scientific and Cultural Organization (Unesco) seems bent on cutting its own throat. The General Assembly of the organization just ended in Belgrade has confirmed that Unesco is no longer the high-minded arm of the United Nations concerned with the general enlightenment that recruited the late Sir Julian Huxley as its first director-general. To be sure, last month's proceedings were less sordidly political than those in the past decade when general assemblies were used by the member states as occasions for isolating Israel from Unesco's general activities. The Belgrade assembly was, rather, cynically political. On two important matters, a combination of developing countries (the "group of seventy-seven") and the Eastern bloc was able to force down the throats of the chief contributors to the Unesco budget two thoroughly bad proposals — a controversial resolution about the procedures to be used for the gathering of news throughout the world, and a scheme for the setting up of a "Special Programme" for planning the technical development of developing countries, a kind of hangover from last year's United Nations Conference on Science and Technology at Vienna. Unesco's budget is to be increased by seven per cent (in real terms) to pay for these new ventures. The industrialized Western states who are the chief contributors have to pay up or get out.

The argument about news-gathering is not merely a technical matter of how news agencies operating internationally should be regulated, but an issue of principle going to the root of Unesco's existence. For several years, developing countries have been grumbling about the unpalatable news of their affairs frequently reported by journalists and news agencies from overseas. Unesco responded by mounting a study of the problem by a commission under Mr Sean McBride, a retired Irish diplomat. The McBride report has been a focus of controversy for the past two years, principally because it gave developing countries reason to believe that they are indeed exploited, and even dealt with unfairly, by the international news agencies. So, the argument goes, there must be a "new information order" to match the "new economic order" for which developing countries (with some justice) have been asking for several years. At Belgrade last month, Unesco was given until 1983 to work out the principles on which such a regime should be based.

But why should this be a black mark for Unesco? Surely the gathering of information is properly within the organization's terms of reference? And surely it is right and proper that it should respond to the wishes of the majority of its members? That is the defence of what Unesco is about. These arguments are nevertheless too facile. They entirely overlook the dangers of admitting that governments have a right to expect news of a kind that is welcome, even flattering. The enterprise on which Unesco is embarked also carries explicit approval for the notion that governments should properly be concerned with the management of the means by which news of their own doings is relayed to the wider world. The fear is that governments will use the Unesco resolution as an excuse for telling journalists what they should say.

It is, of course, well known that member governments differ in their estimation of these dangers. Many socialist states take the view, logical enough, that the gathering of information and its dissemination plays such an important role in society that governments must shoulder the responsibility. Most Western governments, with more or less enthusiasm, follow the opposite principle that a free press is a necessary guarantee of personal

freedom and thus of a just society. The governments of developing countries differ among themselves. Some hanker after the Eastern way but lack the facilities. Others — India is perhaps the most creditable example — put up with a free press without too much complaint. Wherever the truth lies (and there is not much doubt of that), the difference is frankly ideological. By backing one side and not the other, Unesco's members have unwisely — some would say foolishly — committed the organization to an ideological position in a way that must surely conflict with its high-minded principles.

Unesco's special programme for redressing the technical balance between the developing and the industrialized countries of the world is similarly born of ideology. Again, there is no complaint that the topic is outside the organization's terms of reference. Nor is it denied that there is an urgent need of more and of more effective technical and financial assistance for the developing countries of the world. There is yet a chance that the message of the Brandt Commission's study will sink in (see *Nature* 21 February). It does not, however, follow that the nostrums that preoccupied the Vienna conference last year would have been effective even if they had been approved (which they were not), that the notion of a "new technological order", ill-defined as it is, makes any sense and that a specially created Unesco secretariat, politicized as it would be, would be competent to define a strategy for the future. It is not, in any case, as if the United Nations system is short of organizations for fostering technical and economic development. Within its special terms of reference, Unesco might have done a useful job by helping to bring about a better understanding of the sharp differences of opinion that abound on the proper relationship between developed and developing countries on science and technology. By plumping for the solution of the new technological order, the majority of Unesco's members have yet again put ideology before good sense.

Unesco is not well placed to take such risks. Over the years, it has won itself an unenviable reputation for unreality, extravagance and maladministration. Some good things have come out of the splendid Corbusier building in the Place de Fontenoy. Unesco helped to focus interest on Abu Simbel and on the hydrology of Venice. Its efforts to encourage innovation in science teaching and the systematization of scientific bibliographies have been well meaning but not sufficiently energetic to make a mark in competition with other free-wheeling agencies. Other projects, the so-called "Biosphere" programme for example, have been chiefly valuable as sources of largely empty generalizations. It is no wonder that people (and member governments) increasingly ask whether it can be worth its cost.

Unesco would be better placed to run ideological risks if it were less open to complaint about the ordinary conduct of its affairs. The chances are that most of the disaffected Western governments will react to the troubles at Belgrade by resolving to pay more attention to Unesco's business in the years immediately ahead. Few of them would wish, at this stage, to incur the opprobrium of taking the initiative to cut it down to size or even to put it to sleep. But things could change — as the United States Congress will change in January. Unesco may yet find itself in the uncomfortable position of the International Labour Organization, which has not yet recovered from the withdrawal of the United States three years ago. It would be unfortunate, but no by any means the end of the world, if Unesco were to find itself in a similar position. The remedy is in its own hands.

# Academics agonize about weapons labs

## Livermore and Los Alamos up for grabs

San Francisco

In what promises to be another stormy round in a long-running debate, the Board of Regents of the University of California is meeting next week to discuss how it should increase its control of research programmes at the two weapons laboratories which the university runs for the Department of Energy (DoE).

The present five-year management contract for the two laboratories — at Livermore and Los Alamos — runs out in 1982, and preliminary moves to negotiate a new contract with the department have restimulated discussion of the implications of the university's responsibility for the research that underpins a major part of the world's nuclear arsenal.

Last year, the Board of Regents, which is responsible to the state for the university's affairs, rejected a proposal from *ex-officio* member Governor Jerry Brown to remove all military research from the Lawrence Livermore Laboratory, and in September voted to open discussions with DoE for a new contract. The focus of debate has therefore shifted from whether the Livermore Laboratory should be carrying out weapons research at all to how the university should exercise its management responsibilities over this research. In particular, opinions differ about the extent to which the Board of Regents — and possibly outside advisers — should be involved in determining research priorities for the laboratory.

Under the present arrangement the university accepts responsibility for the quality of the research but leaves priorities almost entirely to DoE, a situation which many scientists and administrators at the laboratory are reluctant to see changed. "If a car is running well, you don't tamper with the engine", one Livermore official said last week.

Some members of the university faculty are, however, concerned about the lack of control over military research programmes. The autonomy enjoyed by the laboratories under the protection of the university was described in a report as "so delightful as to border on the licentious". More recently, a group of laboratory staff at Livermore, known as the Society of Professional Scientists and Engineers, has suggested that there should be greater outside monitoring of research.

At the same time, the university is keen to keep a contract which brings in \$4 million a year in management fees, and it

points out that several recent reports, including one prepared by the department's Energy Research Advisory Board, have concluded that it is in the best interests of both sides that the basic links with the university be maintained.

At its meeting last month, the Board of Regents received two proposals for modifying the relationship. Professor William Fretter, the university's vice-president, suggested that the regents appoint a new oversight committee to "provide increased accountability to the general public", and that this committee establish three evaluation committees, one of which would be responsible for establishing research priorities.

The second proposal came from Governor Brown and is based on the report of a committee which the university itself set up in 1978. Like Professor Fretter, the governor also proposes a new oversight committee, but this time assisted by an independent advisory board.

The two proposals agree on many points, but also have significant differences. For example, while the evaluation committees proposed by Professor Fretter would essentially be subcommittees of the oversight committee, Governor Brown's advisory committee would have much greater autonomy, being empowered to request that the oversight committee help it evaluate particular programmes or problems.

The composition of the proposed committees would also differ significantly. The evaluation committees proposed by Professor Fretter would chiefly consist of experts from within and outside the university. In contrast, Governor Brown

contemplates an advisory board of scientists, faculty members, students, health experts, theologians and others.

The president's office is now deciding whether the two proposals can be combined. Otherwise, the choice between the two approaches will have to be made by the regents.

Whatever the result, increased control — at least of research not related to weapons, which forms about half of the work of both laboratories — seems inevitable. The university's president, Dr David Saxon, has already proposed setting up a panel of scientists to recommend research priorities in energy research and other unclassified areas at the two laboratories.

More controversial is the extent to which an oversight committee should be involved in policy decisions about weapons research, which is shortly expected to include work on the MX missile system. Here both university and laboratory officials argue that all such policy decisions must be made at the national level in Washington, and that the laboratories should only carry out Washington's requests.

Critics point out, however, that in the past laboratory officials have been far from neutral in policy debates over weapons research and related areas of arms control. For example, pressures from the two weapons laboratories were significant in reducing the scope of the Comprehensive Test-Ban Treaty now being negotiated in Geneva, while other laboratory officials have been active in the debate over whether to ratify the Strategic Arms Limitation Treaty (Salt II).

David Dickson

## Short commons for Spanish research

A ten-month freeze on research grants for scientists in Spanish universities and the Spanish National Research Council ended on 20 October with the distribution of 3,600 million pesetas (£22 million) to groups in the universities and the research council. The average of £24,000 per group must officially last three years — although the period may in practice be longer. Grants were last awarded in 1976.

The distribution has come in for some severe criticism, particularly from members of the group of 200 leading scientists who, just before the grants were announced, had sent a manifesto to the Minister of Universities and Research describing his policies as "derelict" (*Nature* 23 October, p.674). The group now says that the meagre distribution is no surprise. Spain historically has spent only 0.3 per cent of its gross national product (GNP) on research and development compared with about 2 per cent in other Western countries. Passions have,

however, been stirred by the way in which this distribution has been made.

One member of the group says that a key advisory body has been ignored, and that grants have been awarded by subject panels which were not best qualified to make judgements. The result has been a largely random distribution of money, he claims. Some of these discontents were aired at the meeting on European Economic Community (EEC) science policy held two weeks ago in Strasbourg.

The advisory body, the Gabinete de Estudios, was set up four years ago by the now deputy director-general of the United Nations Educational, Scientific and Cultural Organization, Professor Federico Mayor, to provide baseline studies of science in Spain and to advise the Comisión Asesora de Investigación Científica y Técnica (CACT), which distributed last month's grants. But the Gabinete's recommendations of referees for the grant applications were rejected, said the

manifesto spokesman, and CACT took other advice about the composition of the panels of referees.

One curious feature of the grant-making process is that the director of CACT, Professor Marcos Rico, demanded that nobody who was applying for a grant should serve on a review panel. The manifesto group complains that no scientist worth his salt would not be applying after a year without a research grant. The head of one of the panels has since written to one unsuccessful applicant (who with a similar proposal won DM265,000 from the Volkswagen Foundation) to say that a lottery would have been equally fair.

On the other side, the Ministry for Universities and Research claims that the

Seara — handing out

manifesto group is the naive political tool of the far Right, which wants to unseat the minister, Luis Gonzalez Seara, for his attempt to reduce professorial power with a bill now before parliament.

Seara's chief science adviser, sociologist Narciso Pizarro Ponce de la Torre, said at the Strasbourg meeting that his ministry (like Spanish democracy) was new and that the power of the Francoist professors was great, so that change had to be slow. Even so, the ministry is preparing a major policy statement, the 'livre blanc', on science for May 1981, together with a three-year plan that would multiply university research tenfold. But, said the manifesto group spokesman, the same has been said before, by three successive ministers: he will not believe it until it happens.

The seriousness of this conflict cannot easily be gauged. Narciso Pizarro accepts that a 'more scientific' method has to be found for making the next allocation of grants. He is considering the appointment of international referees to some of the review panels for the next grant allocation in 1983. But he argues that the international community can itself be an inequitable power base for those with access to it, and wants to see a 'just' distribution of funds. So does the manifesto group, although its wish that scientific excellence should be rewarded is seen as elitist in a fledgling democracy. The conflict is between the impatient and the gradualists.

Robert Walgate

## US radioastronomy Thinking big

San Francisco

Following the successful completion and inauguration of the Very Large Array (VLA) telescope in New Mexico last month, US radioastronomers are developing an ambitious scheme that would, in effect, turn the country into a single large radio telescope.

The VLA is designed to study relatively close objects whose distance from the Earth is of the order of thousands of light years. But to study the internal structure of quasars and the nuclei of galaxies the necessary resolution can only be achieved by the use of Very Long Baseline Interferometry (VLBI) in which data from several telescopes are combined to form a single image.

To some extent this can be done by linking existing telescopes, and since 1975 seven US radio telescopes have formed such an array. But there are several disadvantages, including the difficulty of coordinating and correlating data from machines designed and built for different purposes.

The new proposal, which has been developed by scientists from the California Institute of Technology (Caltech) and its Jet Propulsion Laboratory (JPL), is for a transcontinental array of ten 25-metre radio dishes, stretching from Massachusetts to Hawaii and controlled by a single central computer.

Such an array should provide an order of magnitude leap in the important parameters that could be measured compared with the data that can be collected from the present *ad hoc* arrangement. It could be used to provide fine detail radio maps of quasars and galaxy nuclei and also for making precise

measurements of the Earth's rotation, even providing information on plate tectonics.

The scientific and the economic feasibility of such a transcontinental array has now been demonstrated in a Caltech study which concludes that for extragalactic astronomy VLBI is the only tool available for detailed study of the energy sources in quasars and galaxies.

One feature of the Caltech proposal is that the array would be two-dimensional, with radio dishes as far north as Alaska. This spread will make it possible to cover almost all of the northern sky, in contrast to a Canadian proposal for a similar array with radio dishes essentially on a linear axis from Europe to British Columbia.

Two particular aspects of the array would improve performance compared with the present system. First, being able to locate the individual dishes in an optimal arrangement would make it possible to increase the dynamic range by an order of magnitude. This would allow detailed studies of the shape, size and evolution with time of the jets which are emitted from quasars and galaxy nuclei, in particular the acceleration and deceleration of so-called 'knots' which occur within the jets.

The second advantage is that the array would be able to make measurements at frequencies of up to 15–20 GHz, considerably higher than some of the telescopes in the present array can achieve. This will make it possible to look much further down the jets to the surface of the objects from which they are emitted.

Radioastronomers in general are enthusiastic about the proposal for a ground-based array, which has been given top priority for funding in the next decade by the Field Committee responsible for overseeing research priorities in all fields of astronomy.

The main problem, inevitably, will be funding. The Caltech group estimates that the array will cost \$38.8 million, considerably less than other astronomical facilities (VLA, for example, cost \$80 million).

But astronomy, like other fields of basic science, is feeling the pinch. Already the National Science Foundation (NSF) has had to postpone plans for the next telescope on its priority list, a 25-metre dish that had originally been requested for funding in the fiscal year 1981 but failed to survive the budget review process.

There are three other schemes vying for funds. The National Aeronautics and Space Administration (NASA) has been working on plans for an advanced X-ray astronomical telescope, a successor to HEAO 2 and HEAO 3. In addition to the ground-based array, the NSF is already considering proposals for a 10–15-metre optical telescope, including designs that have been submitted by the University of California, the University of Arizona and the University of Texas.

Caltech scientists should have detailed plans ready for potential funding by 1982.

## Any encounters, any kind

Voyager 1, now nearing Saturn, is far from innocent of messages to extraterrestrial civilizations (in which respect the article on page 9 is incorrect). Like its partner, Voyager 2, it carries a phonograph disk of copper (for long life) with sound recordings of greetings in 60 languages, a spoken message from Kurt Waldheim, Secretary-General of the United Nations, sounds of the Earth (natural, unnatural and musical) and a list of the members of the pre-election US Congress.

The disk also contains analogue tracks representing 100 photographs of the Earth and a message from President Jimmy Carter referring to 'our progress towards a single global civilization' and 'our wish to become a member of the galactic community'. Voyager 1 was launched before the seizure of the US hostages in Iran.

and on such a schedule their array would be in operation by 1984–85. If the 25-metre dish is approved for funding next year, as hoped, there will be no conflict. However, if it is postponed again, then relations between what could become rival projects would be more delicate.

Experience has taught supporters of the ground-based array that any debate over who should run the facility ought to be resolved before the funding battle begins. Many feel that proposals for a mid-west telescope floundered because of inter-university rivalry for control. "We are determined not to make the same mistake again", says one radioastronomer.

David Dickson

## Nuclear protests

### Were Croats first?

With the Madrid Conference about to commence its review of the Helsinki Accords on Security and Cooperation in Europe and the Campaign for Nuclear Disarmament recently revitalized in the United Kingdom it is interesting to look back at what was almost certainly the first ever anti-nuclear protest — that of Dr Ivan Supek, a Yugoslav physicist, in 1944, more than a year before nuclear bombs were dropped on Hiroshima and Nagasaki.

Before the war, Supek had been a pupil of Heisenberg. In 1941, after a visit to

impossible the final victory of progressive forces — a victory which Marxist theory stated was inevitable. Therefore such weapons could not exist.

Supek, however, remained unconvinced, and a few months later published his papers from the congress in the Croatian popular science journal *Priroda* under the titles "Developments in Modern Physics" and "Science and Society".

Although at that time his main fear was of the perverted use that the Nazi regime could make of science (biology as well as physics), his stand against nuclear weapons has never wavered. He has from the beginning been an active participant in the Pugwash movement, and is extremely wary of proposals for peaceful uses of nuclear energy (including research), lest they be perverted to military ends.

Vera Rich

## Research councils

### Geological setback

The Department of the Environment will slash a third from its spending on geological science over the next three years, raising a question mark over the future of the Geological Survey of Great Britain, officials of the UK Natural Environment Research Council (NERC) said last week.

NERC was launching its first annual report since Sir Hermann Bondi took over a month ago as the new chairman of NERC (see *Nature* 5 June, p. 349). Bondi had no influence over the report and was much less concerned than his colleagues: "This report is not in my style", he said. "As you know, I'm an eternal optimist."

Bondi favours the Rothschild "customer-contractor" principle, which the report described as a threat. In 1973 NERC lost control of a third of its budget to government departments, following Lord Rothschild's recommendations for a shake-up in government science spending. At the time, the council warned that many of its projects — such as the Geological Survey — which were dependent on a group of customer departments would be vulnerable to the whim of any one of its customers. "It is of little comfort that this forecast is proving correct" says the report.

A quarter of NERC's £20 million contract research income depends on multi-customer contracts. The Geological Survey itself costs about £4.5 million a year, of which the Department of the Environment currently contributes £1.5 million. The survey was established in 1835, and produces near-surface and deep geological maps of Britain, improving them area by area as techniques develop. Some 180 scientist-years are spent each year on the survey, which involves 10 field units and a number of palaeontologists and chemists, mostly at the Institute of Geological Sciences (IGS).

The survey, UK geologists argue, is a national resource, drawn on regularly in

major civil engineering works, for example. But if the Department of the Environment takes too short a view, the value of the survey will be diluted and ultimately lost. A thorough survey for a "sheet" covering an area of 12 miles by 18 miles takes around 25 scientist-years and 5 to 7 years. "So you can't turn on a tap when you need a survey" said Dr Brian Kelk, who heads NERC's geosciences division. The survey is not purely an academic exercise. Dr Kelk argues that the survey must be developed on a continuous basis. It is not possible to predict exactly which areas are likely to prove important; for instance, the massive construction work carried out for North Sea oil terminals on the west coast of Scotland and the Shetlands would probably have been slowed without the geological maps which may have seemed of only academic interest when they were made in the 1920s.

Other bodies in the "consortium" which has managed the survey since Rothchild are the Department of Energy (contributing 5 per cent), the Department of Industry (also 5 per cent) and NERC (60 per cent, through the science vote of the Department of Education and Science). But the consortium will now collapse, with the Department of the Environment cutting its share to 20 per cent and offering its money piecemeal for particular areas and purposes. A new management structure must thus be found for the survey — and one is being sought actively by the director of the IGS, Dr G. M. Brown, who will present his proposals to NERC in two weeks' time. Dr Brown will also have to cope with other Department of the Environment cuts at IGS, where the department is reducing its spending from £3 million (at 1979 prices) this year to £2 million in 1982–83, out of a total IGS budget of £16 million. Staff recruitment, for one thing, will be reduced to a trickle.

Nevertheless, NERC's total income of £56.6 million in 1979–80 will hold roughly constant in real terms in 1980–81, largely through a slight increase in funds from the Department of Education and Science; but there is another problem over the replacement of the council's two research ships, *RRS Shackleton* and *RRS Discovery*. The *Shackleton* is older, and will probably be retired around 1983. The *Discovery* should remain effective until about 1987, but a new ship must be found to replace her if Britain is to maintain her place in oceanographic research, says NERC. This would cost £18–20 million at present prices, plus equipment: and to have her ready for the 1988 season, the order must be placed in 1984 at the latest. But there is no sign of the necessary money being made available — except perhaps if the ship were used jointly by the Science Research Council's Marine Technology Directorate and NERC.

It is here, perhaps, that Bondi's contacts and experience in the Advisory Board for the Research Councils — which advises on

Supek (left) and comrade, 1944

Heisenberg in Leipzig, he said that, although his main interest at the time was solid-state physics, he was able to make an "informed guess" that the Germans were working on both fission and fusion bombs.

Supek made his fears known in June 1944, at a congress of Croatian "cultural workers" (a term which included scientists) held in the newly liberated town of Topusko. His views did not go unchallenged. Several Marxist participants were doubtful that such weapons could exist at all. Nuclear weapons in Nazi hands, they argued, would render utterly

the science vote of the Department of Education and Science — may tell. He is reluctant to challenge the Rothschild principle, to which he still adheres firmly — while recognizing the dangers of multi-customer arrangements. He and his staff will redouble their efforts to get new contracts for support for projects in Third World countries.

Robert Walgate

## London university

### Medical schools stay

Two of the medical school of the University of London, whose survival has been in doubt since March this year, were reprieved last Wednesday (29 October) by a resolution of the university Senate. The decision is regarded, within the university, as a sign that the more far-reaching inquiry into the organization of the university as a whole now under way will be less radical than some have feared.

The two medical schools concerned are Westminster Hospital Medical School and King's College Hospital Medical School (which includes a pre-clinical school at King's College proper and a clinical school at King's College Hospital, in south-east London). The disbandment of the two schools was recommended to the university in March by the report on medical teaching in the university prepared by a committee under Lord Flowers, rector of Imperial College.

The politics of last week's narrow Senate decision have a particular interest for the future reorganization of the University of London. The resolution eventually adopted by the Senate was proposed by Dr Bryan Thwaites, principal of Westfield College, one of the smaller institutions of the university. Thwaites and the others supporting the resolution argued that the university should not attempt to coerce constituent academic institutions into courses of action they found unpalatable.

This line of argument has an obvious bearing on the general inquiry into the organization of the university being conducted by a committee under Sir Peter Swinnerton-Dyer and set up by the vice-chancellor, Lord Annan, earlier this year. One possible outcome of that inquiry is a recommendation that the smaller institutions within the university might be merged with larger college or with each other. If however the principle of self-determination has been established, proposals involving loss of independence are less likely to be seriously put forward.

The battle over the independence of the two medical schools is not yet over. Although the decision may in principle be overturned by the Court of the university, this is unlikely without further consideration. A more likely course is that the Academic Planning Board, to which the issue has been referred, will come to a different decision from that of the Senate last week.

## Séveso scare

### Bloat, not poison

A flurry of fear last week that dioxin had reared its head again at Séveso has quickly abated. The local community was alarmed when 150 sheep died after spending a single night on a forbidden field, out of bounds to grazing animals for the past four years. The dead sheep were part of a flock of 250 driven 50 miles from the dry uplands of northern Italy.

First thoughts had blamed dioxin. The field was one of the most exposed when a chemical factory exploded at Séveso in 1976, distributing dioxin over the neighbourhood, and it had not yet been cleared for farming. (The shepherds say they did not see the notices.) But the sheep died too quickly for dioxin poisoning, and the levels in the field are now thought to be quite low. In fact the Séveso special office, headed by Senator Luigi Noé, was planning shortly to open nearby fields for cereal growing, but these plans were halted after the death of the sheep.

Dead sheep, dead landscape

However, the necropsies now show that the sheep died of bloat — severely distended gut, caused by the over rapid fermentation of wet hay, rye and grass in the stomachs of the hungry animals.

The result has been backed up by analysis of the livers of the dead sheep at the Mario Negri pharmacological research institute in Milan, which first detected dioxin in Séveso goats during 1976. According to Dr Luciano Manara, head of

the drug metabolism laboratory at the institute, the sheep had liver dioxin levels below 1 ng per g — compared with 1 µg per g in the most exposed goats in 1976.

Senator Noé has declared himself satisfied with these results, and has restarted the plans to open the Séveso fields.

Robert Walgate

## Bovine tuberculosis

### Badgers at risk

Tuberculous badgers are more of a threat to themselves than to the cattle they infect. This is the nub of Lord Zuckerman's report on the British practice of gassing badgers, suspended a year ago after protests from conservationists (see *Nature* 28 October). Immediately after the publication of his report, *Badgers, cattle and tuberculosis* (HMSO, £5.20), the Secretary of State for Agriculture, Fisheries and Food announced that the practice of gassing infected badger setts is to be resumed as soon as possible and then reviewed after a three-year trial period.

Bovine tuberculosis is most common in south-west England, chiefly in the counties of Avon and Cornwall. The British badger population is to some extent concentrated in southern England, but the agriculture of the eastern counties is more concerned with cultivation than with cattle-rearing.

Evidence in the Zuckerman report for the association between bovine and badger tuberculosis is largely circumstantial. The incidence of bovine tuberculosis is correlated with that of badger tuberculosis and with the density of the badger population. There is also evidence that transmission from one species to the other is feasible. In Britain, the association (long suspected) became the basis for official policy on badger control only in 1971, after experience in New Zealand suggested that opossums were there a feral reservoir for bovine tuberculosis.

The issue has been contentious in Britain for the past decade. The Badger Act of 1973 gave badgers specific protection over and above the provisions of the Protection of Animals Act of 1911, but the Ministry of Agriculture was given power to control badgers (and even to enter farmers' land for that purpose) by later legislation in 1975 and 1976.

The causative organism of bovine tuberculosis, *Mycobacterium bovis*, is the chief cause of tuberculosis in badgers. The most arresting data in the Zuckerman report are those for the incidence of *M. bovis* infection in badgers. The most extensive series of measurements is that carried out by ministry laboratories of badger carcasses submitted for autopsy, usually after being killed on roads. In south-west England, more than 4 per cent of adventitious carcasses yielded *M. bovis*, while elsewhere in Britain isolation of the bacillus from dead badgers was sporadic and not statistically significant. In another

survey of more than 4,000 badgers, 14 per cent were found to be infected.

The rate of badger infection on farms on which outbreaks of bovine tuberculosis have occurred is often much greater, approaching or even exceeding 50 per cent. The report says that the course of the disease among badgers is that of a virulent infection, with pups especially at risk.

In principle, there is no reason why wild animals other than badgers should not be infected with *M. bovis*, which has been found in small numbers of foxes, rats and moles. The Zuckerman report asks for a continuing survey of the occurrence of *M. bovis* and of other related bacilli, including *M. avium*, which has been found in deer, hares and hedgehogs, in particular.

## Swedish Academy

### \* Plugging Nobel gap

A Swedish industrialist, Dr Holger Crafoord, has given £500,000 — with more to come — to the Royal Swedish Academy of Sciences to institute a new series of scientific prizes in fields of science neglected by the Nobel awards — geosciences, biosciences (emphasizing ecology), mathematics with astronomy, and arthritis. The fund, called the Anna-Greta and Holger Crafoord Fund after Dr Crafoord and his wife, will amount to some £1 million by 1984 and the academy estimates it will yield interest of 13 per cent.

Only one third of the interest, perhaps  
★ £45,000 a year, will be spent on prizes. A quarter will go back to capital, and the rest

will go on research grants, to be awarded by international competition. The details of the award system are being worked out by a special commission, which will report to the academy early in 1981 in the hope that the first awards can be made that year. The intention is to avoid the season of the Nobel awards, traditionally made in late September and early October. There will probably be one prize in a single subject each year, rotating on a four-year cycle.

The subjects emphasized in the new award are the result of a few months' consultation between Crafoord and the academy. Dr Crafoord, who is general director of the biomedical firm Gambro AB of Lund, suffers from rheumatoid arthritis — hence the attention given to that disease.

Asked why he made the awards, Crafoord said last week "I had money enough!" Crafoord owns Gambro, which has some 20 per cent of the world market for kidney dialysis units. He felt he wanted to leave money to science, and asked the academy what fields were short of money. The allocation to research grants, as opposed to prizes, was made at his request. "I chose the academy because it was founded in the seventeenth century — it gives some guarantee that the fund will be maintained."

The academy does not see the awards as a chance to improve on the present system for the selection of Nobel prizewinners. "We are very happy with that" said an academy spokesman. "If we could match it for the new prizes we would be well pleased."

Robert Walgate

## Brazilian biology

### Humus from wood

A scheme for turning sawdust into humus, and exporting 600,000 tons of it to the Middle East, is being developed by Nutri-Humus Laboratories of Sao Paulo. This is the latest step in a long-term plan for liberating Brazilian agriculture from dependence on petro-dollars conceived by the bacteriologist Mario Nogueira de Oliveira, who founded Nutri-Humus 20 years ago.

The company began in a small way, supplying a few Brazilian farmers with the fermentation vessels, worms' eggs and organic fertilizers needed for the process. Now that rising oil prices are making the method economically competitive, and there is increased ecological consciousness, there is large-scale acceptance of the new approach.

On the farm, raw vegetable matter (sawdust, rice husks or bagasse from sugar cane) is spread over the fields at 10 to 20 tons per hectare, mixed with two 60-litre bags of pure humus and "earthworms' eggs" as a "primer", plus a third of a ton of natural phosphate obtained as a by-product of mining in the area. Next comes the novel part of the process — the land is sprayed with four types of brew, labelled enigmatically A, B, C and D.

Being something of an empiricist, and not wanting to release too many details of what might be a profitable enterprise, Nogueira does not explain his methods in full. But the additives include *Rhizobium* species bacteria such as *R. japonicum*, nitrogen-fixers and antifungal agents. It is claimed that the process manufactures organic fertilizer in 60 days instead of the usual 4 years at nature's own pace.

Industrially the plan is to use sawdust and wood chips which are the by-products of the timber industry of the Lages area of Santa Catarina state. The wood is hydrolysed with 0.3 per cent sulphuric acid before use and the exportable end-product is the "organic fertilizer", that is, 60-litre plastic bags containing the final humus breakdown products. This is now being made on fields in the Lages area and its market price is one-tenth that of chemical fertilizers in Brazil. It is hoped that a contract will soon be signed with the Libyan and Saudi governments for the sale of 200 shiploads of humus following the successful demonstration of alfalfa production on sandy terrain using Nutri-Humus.

Nogueira's long-term aim is self-reliance for Brazil's agriculture. He proposes a reduced cultivated area for sugar cane to serve as a generator of organic material. Each hectare of cane would fertilize 30 hectares of land in a year. As well as being freely available and high-yielding, sugar cane contains saccharose which facilitates the fermentations on which the Nutri-Humus process is based. Maurice Bazin

## Franco-Soviet jaunt to Halley?

A joint Franco-Soviet mission to visit Halley's comet in 1985 has been announced. This comes as a surprise to many French astrophysicists, including those already involved in the European Space Agency (ESA) mission to the comet which, it seems, the Franco-Soviet experiment will to a large extent replicate. ESA officials confirmed that there is no possibility of France withdrawing from the European effort — participation is mandatory on all members.

France has always had a special relationship with the Soviet space programme. President de Gaulle was the first and so far the only Western leader to visit the Baikonur space centre. French participation in Soviet launches has included a laser experiment aboard the Lunokhod Moon-rover and a joint ionosphere experiment using high-altitude rockets launched from the Arctic and Antarctic ends of the same line of force. And two French cosmonaut candidates are now in training at the Gagarin space centre.

The propaganda value of these trainees, one of whom will become the first Western European to fly aboard a

Soviet spacecraft, has not been overlooked. At the beginning of October, Moscow radio commentator Boris Belitskii, after censuring the British media for neglecting the significance of the joint Soviet-Cuban flight, claimed that the training of the two French cosmonauts was even more "significant in terms of missed opportunity" for Britain. In the Soviet Union, he said, television viewers could watch cosmonauts carried aloft to work on a space programme geared to human needs, whereas in Britain the only rockets to appear on the television screens were American cruise missiles, plus, of course, science fiction epics.

Belitskii's message was clear — a Britain without US military missiles would be eligible for consideration as a future partner for the Soviet Union in space. He made no mention of the financial cost. Judging from the latest Franco-Soviet proposal, this need not be excessive in cosmic terms. The trip to Halley's comet — including the launching of French balloons above Venus — will cost France a mere 150 million francs (£15 million). Vera Rich

# CORRESPONDENCE

## Malaria vaccines?

**SIR** — Considerable effort is being directed towards producing a practical and effective vaccine against the most malignant human malaria, that caused by *Plasmodium falciparum*. The belief that this is feasible was based on the realization that human malaria induces effective specific immune responses which are protective. The best characterized of these are antibody-mediated, directed against stage and species specific antigens of sporozoites and merozoites and seem to act by preventing the entry of these two extracellular forms into their respective target cells, hepatocytes and erythrocytes.

However, the clinical effectiveness of natural immunity in exposed subjects is partially offset by processes generated by living plasmodia which permit evasion of immune effector mechanisms. These include the bewildering degree of antigenic diversity generated by the parasite as it differentiates through successive stages; also its ability to compromise host immunity through induction of immunosuppression and through polyclonal activation of lymphocytes and probably also by production of soluble antigen. Experimental vaccination with, for example, irradiated sporozoites or non-invasive merozoites, induces more effective immunity than does natural infection, indicating that nonviable forms of the parasite can stimulate protective immunity without activating processes favouring parasite survival.

The logical step from these observations is to develop stage-specific vaccines based on sporozoites and merozoites. The difficulty of obtaining these forms in sufficient quantities for even a restricted trial of adequately standardized material has encouraged detailed investigations into the structure of plasmodial antigens in the hope of identifying those involved in inducing protective immunity. This task was beset with technical difficulties, but the prospects have been transformed by the advent of techniques of somatic cell hybridization to generate cell lines which secrete monoclonal antibodies of defined specificity. The very first clone of antibody secreting cells raised against sporozoites led directly to the isolation of a stage-specific, surface-coat component of molecular weight 44,000 with the potential for promoting immunity to this clinically important stage of infection. With these specific probes it is becoming feasible to attempt the *in vitro* production through DNA cloning of plasmodial antigens having putative protective activity.

It is not surprising that such work should attract the attention of commercial interests, not least from those most recently founded and best equipped to exploit its potential. This intervention gives promise of greatly strengthening the malaria vaccine research effort, but some of its consequences may soon retard progress. Work on a malaria vaccine is unusual in requiring access to materials and facilities so diverse as to demand the collaboration of many laboratories. These requirements include a wide range of adequately characterized and geographically remote plasmodial species, their *in vitro* culture, the use of breeding colonies of

appropriate mosquito vectors, access to those few primate species susceptible to human malaria and eventually the organization of adequately controlled and locally acceptable clinical trials in countries which may have only rudimentary public health facilities. Despite these requirements some institutions are contemplating individually beneficial patent rights on segments of the work. This action already threatens to disrupt in part the complex web of collaborative work so central to success.

Malaria menaces over a third of the world's population and is confined almost exclusively to developing countries. There are around 150 million cases per year and over a million African children die annually of the disease. A recent intensive survey has shown that in the vast African savannah no known method of prophylaxis, however thoroughly dispensed, can in practice be effective. Elsewhere, for example in India and Sri-Lanka, it has proved impossible to sustain prophylactic measures and malaria is alarmingly resurgent. The cost of a developed malaria vaccine can never be recouped from the relatively impoverished countries which require it most urgently. Its manufacture and distribution will inevitably require massive subsidy from international governmental and charitable funds. Under these circumstances can any institution justify a claim to benefit individually from a restricted aspect of work, however important, which contributes to the development of a malaria vaccine? Procedural agreement is urgently required in this area of research. Representatives of major organizations involved should meet together forthwith under appropriate international auspices and agree a moratorium on all patent rights relating to the development of a human malaria vaccine. Is it really naïve to believe that this enterprise cannot be sustained solely on the basis of its scientific feasibility and enormous practical potential for the health of mankind?

London SE1, UK

## Nobel Prize rules

**SIR** — Your editorial on changing the Nobel Prize rules (*Nature* 23 October, p.667) is right on all points. However, it does not mention one vital question — the statistics of sampling.

One way that the Nobel Foundation uses to select candidates is to write at random to about 50 universities for proposals. This list is different each year and comprises a sample of the about 900 universities around the globe (*Encyclopaedia Britannica*, *Micropaedia X*, pp.888-1007). As most of these universities are likely to have a chair in nuclear physics, but only about 10% one in spectroscopy, less than 10% in flow phenomena (hydro- and aerodynamics . . .); less than 5% atmospheric physics; less than 2% aerosol physics etc., the odds that a nuclear physicist will get the letter and nominate somebody within his own field, are incomparably greater than for any other branch of physics.

**Proof:** Between 1950 and 1973, 16 Nobel prizes went to some aspect of nuclear physics, 3 were awarded for low-temperature phenomena; 3 for optics; 2 for quantum

electrodynamics and 1 each for magnetism and semiconductors. Probably similar biases exist in chemistry and medicine.

In conclusion: the Nobel Prize goes by preference to the disciplines with the largest number of scientists. In other words, it is biased towards specialities best endowed with funds. This means that governmental budgeting interacts with the award.

It is surprising that such a select scientific body should not be aware of such a basic sampling error. More than a sampling error; this "pseudorandomization" goes against Nobel's will. At the end of the nineteenth century, physics was comprehensive and subdivision in specialities almost unheard of. Since then, electronics, atmospheric physics, rocketry, astrophysics and many, many other branches have become so detached, that scientists working in such areas are almost excluded from being considered for the prize.

Institut National de Recherche  
Chimique Appliquée,  
Brétigny, France

## Fungal food

**SIR** — The recent article on fungal foods (*Nature* 4 September, p.6) states that the protein gap that was believed to exist in many developing countries has now been declared a myth. I have discussed a similar problem with Mr J. Todd, Executive Assistant to the Unitarian Service Committee of Canada — a Canadian charitable organization engaged in overseas relief and development in cooperation with governments of the least-developed countries. These countries are specifically chosen on the basis of a per capita income being less than \$200 per year. The agency is working in six such countries.

Mr Todd's description of the protein shortages in the many communities in which he works and the desperate need for protein in a wide variety of forms contrasts sharply with your statement. Although such countries are probably unable to buy protein from overseas, the lack of demand based on such inability can surely not be taken as an absence of need.

P.J. HEALD

Memorial University of Newfoundland,  
St John's, Newfoundland, Canada A1B 3X7

## ACHÉ uses

**SIR** — What, pray, is wrong with the determination of any government to attempt to protect its citizens, be they either soldiers or civilians, against the use of "nerve gas" (organophosphorus) weapons? How can this be thought of as "distortion of technology"? R.G. Elles *et al.* (*Nature* 9 October, p.480) are adopting a stereotyped "holier than thou" attitude more appropriate to the behaviour of our "Praise-the-Lord Barebones" forebears of the post-Civil War period — "smelling-out" evils when they would be better occupied in haranguing protest meetings of a non-scientific nature; such letters are inappropriate for a science-based *Nature*.

Tolworth Laboratory, Tolworth, UK

## NEWS AND VIEWS

## A close look at Saturn

from Philip Campbell

No photograph can do justice to what must surely be one of the most serenely beautiful sights in the solar system — Saturn and its ring system. Just over three years after launching, and having already revolutionized planetary studies with its exploration of Jupiter and its moons, Voyager 1 is about to begin the second exploration by spacecraft of Saturn — planet, rings and moons. The spacecraft's closest encounter will occur at 2345 GMT on 12 November at a distance of 124,200 km; the next two weeks, therefore, should provide a feast for astronomers and, no doubt, a fillip for NASA, troubled by escalating shuttle costs and by repeated budget cuts.

Voyager's encounter is the second of three. The first was by Pioneer 11, just over a year ago. Next August, Voyager 2, carrying similar instrumentation, will carry out a series of investigations complementary to those of Voyager 1. The trajectory of Voyager 1 has been designed to include a study of Titan, Saturn's largest moon, while the path of Voyager 2 is already set for Uranus and, it is hoped, Neptune. For that spacecraft, Saturn is, so to speak, an interesting view on the way. Voyager 1, on the other hand, will eventually pass out of the solar system without further known encounters — and without the hitherto obligatory message to exceedingly intelligent extraterrestrials.

Saturn's rings were first recognized by Huygens in 1656. From the earth, two rings can be seen most easily, rings A and B, separated by a gap known as Cassini's division. Following Pioneer 11, the number of distinct rings now known is five: in order of increasing orbital radius they are labelled C, B, A, F and E. Ring F is very narrow and was discovered by Pioneer 11, while ring E is wide and tenuous, extending from about 2.4 to 5 or 6 Saturn radii ( $R_s \approx 60,000$  km) from the planet. (The existence of ring D, previously suggested by ground-based observations to be inside ring C, was not confirmed by Pioneer 11.) The number-density of particles varies considerably from ring to ring, but ground-based observations and an analysis of Pioneer 11's trajectory both indicate that the rings consist predominantly of low-density particles, covered with or consisting entirely of ices of  $H_2O$  and  $NH_3$ . Moreover, ultraviolet measurements from the International Ultra-Violet Explorer

satellite and from Pioneer 11 have revealed that the rings are surrounded by an envelope of atomic hydrogen, possibly generated by photo-dissociation or the sputtering of the ice molecules.

Saturn's rings pose many problems. How did they form and evolve? Whether the rings originated in the tidal destruction of a moon or are a remnant of the proto-planetary nebula, several questions arise. Thus Cassini's division is known to occur close to the 2:1 orbital resonance of one of Saturn's smaller moons, Mimas. (That resonance is at the radial distance from Saturn at which a particle will orbit twice in the time it takes Mimas to orbit once.) One might expect a gap to appear at such a radius because the repetitive gravitational perturbation of Mimas would act so as to remove the particle from its orbit. But how is it that Mimas, only 350 km in diameter, can clear a division about 10,000 km in extent? And why is the division offset on the outward side of the Mimas resonance? Another question concerns the narrow F ring of Saturn — a question much stimulated by the discovery of other narrow ring systems around Jupiter and Uranus. A ring once formed should flatten and spread as a result of random collisions between the ring particles. Why has this not happened around Jupiter and Uranus? And why does the A ring of Saturn exhibit asymmetric spatial variations in brightness when viewed from the earth?

Whatever the answers to these questions — and several have been suggested over the past few years — they certainly involve interactions between the rings and Saturn's satellites. Two possible clues would be the discovery of moons orbiting within the ring system or the detection of density waves in the rings themselves\*. The fact that spoke-like features have already been detected within the rings by Voyager 1 is a promise of things to come.

Voyager 1 is equipped for several different investigations of the rings. Apart from the two television cameras (which are sensitive enough to detect clumping within the rings but not individual particles), an infrared radiometer will be used to examine the brightness-temperature of particles as sensed in different relative positions of spacecraft, particle and the Sun, and also to monitor the rate at which the particles cool once they have entered the shadow of

Saturn. These measurements should yield particle sizes and compositions. An ultraviolet spectrometer will examine the hydrogen envelope of the rings. Finally, the spacecraft radio telemetry links will be monitored as the spacecraft, after the closest encounter, passes behind the planet and reappears behind the rings. Measurements of refraction and absorption of the radio waves by the rings should reveal details of the larger ring particles together with the overall ring thickness, known to be less than a few kilometres and possible only a few metres.

The body of Saturn itself will be investigated by the same techniques. Analysis of the spacecraft trajectory (monitored by the Doppler shift of the radio telemetry signals) will allow better values of Saturn's mass and gravitational moments to be calculated, enabling a density profile of Saturn's interior to be deduced. The post-Pioneer picture is of an oblate spheroid only 95 times heavier than the earth (although more than 800 times the volume) with one-fifth of the mass concentrated in a rocky core about twice the size of the earth. The core is thought to be surrounded by a layer of metallic hydrogen out to half the radius, beyond which is a gaseous envelope consisting predominantly of hydrogen and helium.

To refine this model, it is hoped that Voyager 1 will provide more details of Saturn's temperature structure and internal rotation. Pioneer 11 shed very little light on the question of rotation. Although the rotation period of the outer atmosphere is known to be about 11 hours, no indication was found of the inner rate. Had Saturn's magnetic field, discovered by Pioneer 11, been inclined to Saturn's axis of rotation, the internal period would have been easily determined. Unlike any other known planetary body, however, the magnetic field and rotation axes are aligned to within  $1^\circ$ . Voyagers 1 and 2 carry plasma and plasma wave detectors, magnetometers and radio receivers to investigate further the magnetic field and its interaction with the Solar Wind. (For a recent detailed discussion of the magnetosphere, see Cowley, *News and Views*, **Nature** **284**, 302; 1980.)

Visual observations of Saturn's atmosphere are greatly hampered by a thick ammonia haze, thought to be formed deep within the atmosphere but spread to considerable heights by convection. Cloud bands have been observed, and Pioneer 11 detected several features found on Jupiter

\*Note added in proof: Two new satellites designated S13 and S14, have been discovered, one on either side of the narrow F ring. This may be consistent with a ring-confinement mechanism suggested by Goldreich and Tremaine (*Nature* **227**, 97; 1979).

to be characteristic of high wind shear. The much more sophisticated imaging cameras of the Voyagers, together with their facilities for detailed infrared and ultraviolet mapping and spectroscopy, should greatly improve understanding of the composition of the atmosphere and of its structural variations over the entire planet. At the time of writing, spot-like features have already been discovered.

The prospect of a close look at Saturn's moons must have the Voyager team salivating in anticipation. Will the outcome be as startling as that of the visit to Jupiter? The moons to be investigated are (in order of decreasing orbital radius) Iapetus, Titan, Rhea, Dione, Tethys, Enceladus

and Mimas. These bodies range in size from 175 km (Mimas) to 800 km (Iapetus), Titan standing out at 2,915 km. They will all be mapped optically and scanned in the infrared and ultraviolet to determine surface temperatures and to detect possible gaseous emissions in molecular, atomic or ionized form. The infrared radiometer will also observe an eclipse of Rhea by Saturn; the cooling should provide some clue to the thermal properties and structure of the satellite's surface.

Titan is, as far as is known, alone among Saturn's moons in possessing a substantial atmosphere. No surface features have yet been detected. Ground-based observations do however suggest that Titan's reflec-

tivity, contrary to what would be expected from a gaseous atmosphere, decreases with increasing frequency, so that Titan appears reddish in colour: this has been interpreted as a manifestation of a high-altitude aerosol layer. On the structure and composition of the atmosphere of Titan, it is agreed that methane, ethylene and ethane are present, and Pioneer 11's ultraviolet instrument detected an extensive atomic hydrogen cloud surrounding Titan and possibly extending around part or all of its orbit. The presence of nitrogen in the atmosphere is a source of controversy. Voyager 1, approaching within 4,000 km of Titan, should certainly resolve these problems. No doubt it will throw up many more. □

## How much genetic variation?

from J.S. Jones

WITHOUT genetic variation, evolution cannot take place. The measurement of the extent of polymorphism is hence a prime task for evolutionary biologists, and a variety of genetic and biochemical techniques have been used to this end. Brown<sup>1</sup> has recently found extensive genetic polymorphism in the mitochondrial DNA of man by using a restriction endonuclease analysis which detects individual differences in the DNA sites susceptible to enzyme degradation. Similar polymorphisms exist in human nuclear DNA<sup>2</sup>. Although the study of polymorphism in the structure of the DNA itself is likely to be a time-consuming affair, improvements in the methods available for the study of proteins have already greatly altered our view of genetic variation at the level of the gene product. This new information has important implications for evolutionary theory.

Gel electrophoresis, which utilizes the migration of proteins in an electric field to detect small differences in their charge and shape, can be used to estimate the proportion of a randomly chosen sample of gene loci which is polymorphic. Simple one-dimensional electrophoresis of a sample of loci coding for soluble enzymes was first carried out about fifteen years ago using *Drosophila pseudoobscura* and many organisms have now been surveyed<sup>3</sup>. In general it seems that about a quarter of the loci tested show genetic variation. Most polymorphic loci have rather few alleles; two or three is the norm although there are occasional loci with up to ten.

The unexpected discovery of widespread genetic variation led to a controversy as to whether protein polymorphism is actively promoted by natural selection, or whether it is largely 'genetic garbage' without much evolutionary relevance. Biochemists and

some theoretical biologists have tended to emphasize the importance of selection, but a number of widely discussed mathematical models incline towards the latter view<sup>4</sup>. In general, theories of the selective maintenance of molecular polymorphism find it difficult to accommodate very large amounts of variation, as such theories depend on, for example, differences in fitness between heterozygotes and homozygotes, or differences in the ability of the various alleles to survive in different ecological niches. As the amount of polymorphism increases, these differences must become vanishingly small. Theories of selective neutrality, however, depend largely on two parameters, one of which (the mutation rate) is very small, while the other (population size) may be very large. Both are difficult to measure, but it is clear that, at least in organisms with large populations (such as *Drosophila*), the neutral theory must predict that while many loci might be invariant, others should have very many alleles. The electrophoretic techniques used until recently, however, have demonstrated a rather limited range of variation over different gene loci and have also shown that the majority of enzyme polymorphisms have rather few alleles. Also, according to a theory of selective neutrality of protein polymorphism, closely related species (which share a common ancestor but which have been unable to exchange genes for many generations) are expected to accumulate a different series of alleles because of the action of a different set of random processes over time. This does not seem to be the case; in *D. pseudoobscura*'s sibling species *D. persimilis*, nearly 90 per cent of the polymorphisms detected by simple electrophoresis show identical patterns of genetic variation, although the last gene interchange between these species occurred several million generations ago<sup>5</sup>.

These observations led many biologists

to believe that molecular polymorphism must be actively maintained by natural selection, although the details of the process remained obscure. However, new improvements in the technique of electrophoresis have led to a renewal of support for the theory of selective neutrality. First (as recently discussed by Edwards and Hopkinson<sup>6</sup>) most speculation has been based on data from a very biased sample of gene loci, which ignores structural proteins in favour of genes coding for soluble enzymes. Structural proteins are the most abundant molecules in the cell. Use of the very sensitive new technique of isoelectric focusing in one direction, followed by electrophoresis of the molecules dispersed through the gel at right angles to the focusing path (a method which can detect single charge changes), shows that structural proteins have almost no genetic polymorphism. Estimates of genetic diversity based only on a small sample of enzyme loci are therefore very misleading. In addition, there are serious limitations in the techniques used in enzyme electrophoresis. It has always been accepted that electrophoresis cannot detect all amino acid substitutions. Electrophoretically homogeneous classes of *Drosophila* enzymes are genetically variable in, for example, their resistance to heat treatment and in their ability to form dimers<sup>7,8</sup>. However, only in the last three years has it been realized just how weak the traditional methods of gel electrophoresis may be in detecting enzyme polymorphisms.

Singh, Lewontin and Felton<sup>9</sup> describe some inelegant but practical developments of this technique which they have used to detect new enzyme polymorphisms in *D. pseudoobscura*. They worked first on the xanthine dehydrogenase (*Xdh*) locus. Simple electrophoresis at pH 8.9 on a 5% polyacrylamide gel had revealed only six alleles at this locus. However, sequential analysis of apparently homogeneous

J.S. Jones is in the Department of Genetics and Biometry at University College London, UK.

**Fig. 1** Sequential analysis of an apparently homogeneous xanthine dehydrogenase allele in *Drosophila pseudoobscura*. In all the inbred lines studied, six alleles were revealed in the first set of electrophoretic conditions. After each of the lines were examined on gels of 7% concentration (rather than 5%), 13 variants were discovered. Further examination of these on a 5% gel at pH 7.1 revealed 11 more alleles, and subsequent analysis on a 7% gel at this pH gave 27 genetically different forms. Ten further alleles were distinguished by studying inherited differences in the enzyme's heat stability. Sequential analysis increases the amount of polymorphism detected by six times.

inbred lines on gels of different concentration and pH revealed many previously undetected alleles (Fig. 1). This technique distinguishes 37 alleles, instead of the six previously detected. As only 146 genomes from nature were examined, the total number of alleles at the *Xdh* locus may be even greater.

Sequential electrophoresis does seem to detect most amino acid substitutions. The complete amino acid sequence of many mutant haemoglobins is known; one-step electrophoresis lumps together these different haemoglobins into a series of genetically heterogeneous classes<sup>10</sup>. However, sequential electrophoresis allowed 17 of 20 mutant haemoglobins<sup>11</sup> to be distinguished. This method has now been used on several enzyme systems in *D. pseudoobscura* and *D. melanogaster*<sup>12-15</sup>. Some, but not all, loci have shown a great increase in the extent of their genetic polymorphism. The locus coding for aldehyde oxidase, which was previously thought to have very little genetic variation, is now revealed to possess 16 alleles, while that for esterase-5 increases from 13 to 32. Hexokinase-1 and octanol dehydrogenase show almost no increase in the number of alleles when the new methods are applied. There are no obvious associations between the extent of this newly discovered polymorphism and the enzyme's molecular weight or biochemical function.

These improvements in technique have greatly altered our view of molecular polymorphism. On the one hand there exists a class of structural proteins which are almost invariable, while on the other at least some soluble enzymes show a very high level of genetic variation. This observation accords well with the latest predictions of theoreticians who feel that most molecular polymorphism is not actively favoured by natural selection. The recent models of Kimura<sup>16</sup> and of Ohta<sup>17</sup> incorporate weak natural selection acting against slightly deleterious mutations but

suggest that most mutants have almost no effect on the fitness of their carriers. Structural proteins are highly invariant as they are closely interlocked with each other and have a low tolerance to mutations which change their shape. Any mutants are removed by natural selection. Membrane-bound enzymes are also quite dependent on accurate steric relations with other molecules in the membrane and can thus tolerate only a small amount of polymorphism. Soluble enzymes such as xanthine dehydrogenase, however, are subject to few such constraints; most of the changes in amino acid sequence which result from mutation have no effect on the molecule's function and persist for a period which depends only on the accidents of sampling. Animals which maintain large populations will accumulate very many alleles at such loci, and there is no need to argue that each protein polymorphism is actively maintained because of its biologically useful role.

On previous estimates, *D. pseudoobscura*'s sibling species *D. persimilis* appeared to possess three *Xdh* alleles, two of which were shared with *D. pseudoobscura*<sup>5</sup>. Their close resemblance had been used to suggest that the polymorphism was conserved by natural selection even after speciation. However, when this locus was examined using sequential electrophoresis, 23 alleles were found in a sample of 60 *D. persimilis* genomes<sup>18</sup>. Only three of these are shared with *D. pseudoobscura*, and only one is at all common in both species. The two species, although closely related, have therefore diverged almost completely at this locus since gene exchange was interrupted by speciation. It seems more reasonable to interpret this difference as resulting from a balance between the random origin and extinction of selectively equivalent alleles within each species than to postulate that *pseudoobscura* and *persimilis* (which often occur in the same place) are subject to a completely different set of selective forces.

The existence of the patterns of genetic variation discussed here is not in itself a proof that natural selection is unimportant in maintaining molecular polymorphism. There is experimental evidence for differences in the fitness of electrophoretic alleles at some enzyme loci<sup>19-21</sup> and it is possible that even the dozens of alleles now known to exist may each be found to respond to natural selection, or that new theoretical treatments will show how such extensive polymorphism may be selectively maintained. However, the new data on molecular polymorphism and the cloning a polymorphic enzyme locus in *D. pseudoobscura* into *Escherichia coli*<sup>22</sup> (which may enable large quantities of purified enzyme protein to be produced for further analysis of hidden genetic variation) show that — as so often before in the study of evolution — the experimental cat is among the theoretical pigeons. □

# Flat-spectrum radio sources: victims of a conspiracy?

from Alan P. Marscher

IN early surveys of the radio sky, taken at wavelengths in the 100-metre range, radio astronomers found that most extragalactic radio sources appear very similar to one another. These objects, identified with radio galaxies and quasars, exhibit spectra which have steep negative slopes, that is the radio flux decreases sharply with increasing frequency. However, later surveys performed at centimetre wavelengths yielded a large number of so-called 'centimetre-excess' objects whose spectral slopes are positive, zero, or undulating. K. I. Kellermann and I. I. K. Pauliny-Toth (*Astrophys. J. Lett.* **155**, L71; 1969) interpreted this to be the result of a superposition of several discrete, compact components, each of which exhibits a turnover in its spectrum at a given wavelength below which the synchrotron emission is self-absorbed. Subsequent observations with very-long-baseline interferometers (VLBI) confirmed that these centimetre-excess sources are indeed very compact, with angular sizes often smaller than 0.001 arc s.

The difficulty with the superposition hypothesis lies in the large number of radio sources whose spectra are both quite flat and rather smooth. A random distribution of several self-absorbed components should yield a much larger percentage of undulating spectra than are observed (D. B. Cook & S. R. Spangler *Astrophys. J.*; in the press). This situation has led several authors to suggest that the flat-spectrum sources are produced by a single component whose magnetic field and relativistic electron density decrease with distance from the centre. In this way, a single, inhomogeneous component mimics the spectrum emitted by an infinite distribution of concentric, uniform components and produces a smooth, flat

spectrum (J. J. Condon & L. L. Dressel *Astrophys. Lett.* **15**, 203; 1973).

One such flat-spectrum radio source, the BL Lacertae object PKS0735 + 178, was suggested by A. P. Marscher (*Astr. J.* **82**, 781; 1977) to be a prime candidate for a study to determine which point of view is correct. Its radio spectrum in 1977 was, to within observational errors, perfectly flat over more than two decades of frequency. It was suggested that multi-wavelength VLBI observations would allow one to differentiate between models involving multiple, uniform components and those invoking a single, tapered component.

Several groups have performed these critical observations, and the results are now being published. W. D. Cotton *et al.* (*Astrophys. J. Lett.* **238** L123; 1980) have obtained VLBI observations of PKS 0735 + 178 at four wavelengths — 2.8, 3.7, 11–13 and 50 cm. Although their data at any given wavelength are rather limited, they do, in fact, clearly indicate that this radio source is composed of several distinct, compact components, in line with the superposition hypothesis of Kellermann and Pauliny-Toth. Other observers have obtained more detailed data at various frequencies, with a general picture of the source which basically agrees with the Cotton *et al.* interpretation (A. P. Marscher & D. B. Shaffer *Astr. J.* **85**, 668; 1980; L. B. Bååth *et al. Astr. Astrophys.*; in the press). Of particular interest are the detailed 6-cm observations of Bååth *et al.* (see Fig. 1). These authors find that the structure of PKS0735 + 178 is rather complex, consisting of two compact components plus a more diffuse, jet-like feature extending past the weaker hotspot. In addition, there is a weak, even more diffuse, resolved emission region. Thus, as Cotton *et al.* remarked, this flat-spectrum

radio source seems to be the result of a 'cosmic conspiracy' of several compact components which, when superposed, manage to produce a smoothly varying, flat spectrum.

An important clue to the resolution of this conspiracy might lie in the remarkable similarity in appearance of the radio maps of PKS 0735 + 178 and the two well studied objects 3C273 and 3C345 (A. C. S. Readhead *et al. Astrophys. J.* **231**, 299; 1979). All three sources contain a bright, unresolved component, with a jet-like feature emanating to one side of this hotspot, plus one or more 'knots' of enhanced emission embedded in the jet. R. D. Blandford and A. Königl (*Astrophys. J.* **232**, 24; 1979) have interpreted the bright, unresolved component to be the narrow end of a synchrotron-emitting plasma beam, the fluid in which is moving relativistically. The more diffuse jet is then just the fanned-out extension of this beam (which we are viewing nearly end-on, since this configuration enhances the brightness, making such a source more likely to appear in a flux-limited survey of radio sources). The secondary knots are formed through either some instability in the beam or interaction with cooler gas which the beam encounters. If this picture is correct, one would expect all of the components to be physically associated, having been created one way or another by the relativistic beam. The beam itself is smoothly inhomogeneous, with density and magnetic field strength decreasing as the beam widens. Components appearing downstream might then be related by some simple scaling law to those observed upstream. The beam might thus be capable of modulating the physical parameters of the various components in the source such that they 'conspire' to emit a smooth, flat radio spectrum.

Since the beam is smoothly inhomogeneous, the size of the component at its narrow end should appear to increase with wavelength (see A. G. de Bruyn *Astr. Astrophys.* **52**, 439; 1976; A. P. Marscher *Astrophys. J.* **216**, 244; 1977). This should cause the separation between the bright, unresolved hotspot and secondary knots to decrease somewhat with wavelength. Further detailed multi-wavelength VLBI observations should be capable of determining whether this is, in fact, the case, and thereby test the model.

Finally, it is worthwhile noting that the two objects whose radio structures closely resemble PKS0735 + 178, 3C273 and 3C345, both exhibit rapid changes in the separation of their components. If the distances to these quasars are determined through a cosmological interpretation of the optical redshifts, using a standard

**Fig. 1** Radio map at 6 cm of the compact core of PKS0735 + 178. Easily spotted on the map are the bright, unresolved component, the secondary, compact knot to the north-east, and the more diffuse jet, also extending to the north-east. The larger, diffuse component is resolved out on this scale and hence does not appear. From Bååth *et al.* (*Astr. Astrophys.*; in the press).

Alan P. Marscher is a Postgraduate Research Physicist at the Center for Astrophysics and Space Sciences, University of California, San Diego.

Friedmann cosmology, the observed angular velocities of separation correspond to speeds far in excess of the speed of light (see M. H. Cohen *et al.* *Nature* **268**, 405; 1977). The relativistic beam model mentioned above can explain this phenomenon as a consequence of shortened observed arrival intervals of successively emitted wave fronts. This is caused by the motion of the emitting plasma, which approaches

the observer almost as rapidly as do the radio waves (see M. J. Rees *Nature* **211**, 468; 1966). From the above discussion, one can therefore predict that PKS0735 + 178 should also be engaged in such 'superluminal' expansion. Further VLBI monitoring of this source should allow radio astronomers to test this prediction and thereby increase our understanding of compact radio sources. □

## Hot foot

from Clive Lloyd

CONSIDERING its location at the boundary between cell and environment, it is not surprising that the fibroblast's focal adhesion plaque or 'foot' has become a fashionable meeting point for a whole gaggle of animal cell biologists. The reasons for investigating the foot by interference reflection microscopy are diverse — the study of microfilament bundle attachment, cell locomotion,

morphology and virus infection — but in coming together at this site, these studies raise universal issues of cell behaviour and growth control.

In a previous article (News & Views *Nature* **279**, 473; 1979), it was reported that extracellular fibronectin and cytoplasmic microfilament bundles had been seen to be co-linear across the membrane suggesting that  $\alpha$ -actinin provided the linkage between

microfilament and membrane in such an assembly. However, research moves so quickly in this field that, already, several refinements are required of this model.  $\alpha$ -actinin does not seem to occur sufficiently close to the dense plaque of epithelial *zonulae adherentes* junctions for it to be the mediator of actin's linkage to the membrane (Geiger *et al.* *Proc. natn. Acad. Sci. U.S.A.* **76**, 2833; 1979). Further work is required to define its location as it is detected within analogous focal adhesion plaques isolated from the cell body (Badley *et al.* *Expl. Cell Res.* **117**, 231; 1978; Rohrschneider & Shriver *Eur. J. Cell Biol.* **22**, 521; 1980). The current view seems to be that  $\alpha$ -actinin collects actin microfilaments laterally to form bundles — a function also tentatively assigned to a new 130 K protein first found as a contaminant in preparations of gizzard  $\alpha$ -actinin. When used to stain cultured chicken cells, antibodies raised against this protein (Geiger *Cell* **18**, 143; 1979) produce a punctate pattern at the ventral surface. These sites turn out to be focal adhesion plaques and Geiger concludes that "the 130 K protein plays a more direct role than either  $\alpha$ -actinin or tropomyosin in the association of actin filaments with the cell membrane". In addition, the protein has been shown to terminate microfilament

The articulating photophone. The transmitter.

The selenium receiver.

## 100 years ago

### BELL'S PHOTOPHONE

By the courtesy of Prof. Graham Bell we are at length able to do somewhat ampler justice to his latest discovery than has hitherto been possible. He has supplied us with certain details not hitherto published, and has also furnished us with drawings of his apparatus and experiments.

Our readers are already aware that the object of the photophone is the transmission of sounds both musical and vocal to a distance by the agency of a beam of light of varying intensity; and that the first successful attempts made by Prof. Bell and his co-labourer, Mr. Sumner Tainter, were based upon the known property of the element selenium, the electric resistance of which varies with the degree of illumination to

which it is exposed. Hence, given a transmitting instrument such as a flexible mirror by which the vibrations of a sound could throw into vibration a beam of light, a receiver consisting of sensitive selenium forming part of an electric circuit with a battery and a telephone should suffice to translate the varying intensities of light into corresponding varying intensities of electric current, and finally into vibrations of the telephone disk audible once more as sound. This fundamental conception dates from 1878, when in lecturing before the Royal Institution Prof. Bell announced the possibility of hearing a shadow fall upon a piece of selenium included in a telephone circuit. The photophone, however, outgrew the particular electrical combination that suggested it; for not the least of the remarkable points in this research is the discovery that audible vibrations are set up in thin disks of almost every kind of material by merely throwing upon them an intermittent

light. Hence in theory, if not in practice, the receiver may be reduced to the divine simplicity of a mere disk of vulcanite or of zinc; on one side of which the listener listens.

We may classify the forms of photophone under two heads, as (1) articulating photophones, and (2) musical photophones; the former being able to transmit speech because they work by beams of light whose intensity can vary in undulatory fluctuations, like those of vocal tones; the latter being able to transmit simple musical tones only, since they work by mere interruptions of a fixed beam of light. The greatest distance to which articulate speech has yet been transmitted by the selenium-cell-photophone is 213 metres, or 233 yards.

Whatever be the future before the photophone, it assuredly deserves to rank in estimation beside the now familiar names of the telephone and the phonograph. From *Nature* **23**, 4 November, 15, 1880.

bundles (in a study which suggests a relationship between the 130 K protein, fibronectin and microfilament bundles, Burridge & Feramisco *Cell* **19**, 587; 1980), and is found at three varieties of tissue junction (Geiger *et al. Proc. natn. Acad. Sci. U.S.A.* **77**, 4127; 1980) and at broad areas of close contact between cultured rat myotubes and glass coverslips (Bloch & Geiger *Cell* **21**, 25; 1980). Its characteristics do not, however, suggest it to be of the integral type which could span the membrane. In fact, it is reported to be virtually nonexistent in isolated HeLa plasma membranes which do contain actin (Burridge & Feramisco *Eur. J. Cell Biol.* **22**, 350; 1980) — properties which hint at a role for the 130 K protein in consolidating microfilaments into bundles rather than linking them to membranes.

This leaves open the question of what actually links actin to the membrane. There are doubts, too, about whether fibronectin is the extracellular limb of the trans-membranous assembly. EM sections had shown that actin microfilaments and fibronectin fibrils are co-linear and come very close to touching across the membrane (Hynes & Destree *Cell* **15**, 875; 1978; Singer *Cell* **15**, 675; 1979). Fibronectin is also found to be concentrated at isolated feet (Badley *et al. Expl Cell Res.* **117**, 231; 1978). Now, by taking double exposures of immunofluorescence (to reveal fibronectin) and interference reflection (to reveal focal adhesion plaques), Birchmeier *et al. (Proc. natn. Acad. Sci. U.S.A.* **77**, 4108; 1980) demonstrate that fibronectin is absent from the foot. Geiger reports a similar conclusion (*Eur. J. Cell Biol.* **22**, 350; 1980). An obvious distinction can be made between the techniques that have localized fibronectin at the foot and those that have not — the former either slice or isolate the target site whereas the latter rely on the ability of antibodies to penetrate stable adhesion plaques borne upon whole cells. Questions of accessibility are bound to be prominent in the coming debate.

In attempting to dissect the molecular anatomy of cell/substratum interactions, there is a natural preoccupation with the foot and its attendant musculature but this is not the only relationship that a cell strikes with the substratum. Fibroblasts which migrate out from pieces of embryonic chick heart are highly motile but this locomotion is based on the formation of the broad, unfocused and transient close contacts which are associated with a diffuse actin meshwork (Couchman & Rees *J. Cell Sci.* **39**, 149; 1979; see also, Abercrombie *et al. Expl Cell Res.* **67**, 359; 1971; Badley *et al. J. Muscle Res. & Cell Motility* **1**, 5; 1980). It is some time later (24–48 h) that the migrating cells become stationary and form the more stable focal adhesion plaques which terminate stress fibres. This conversion from the motile to the sessile condition also coincides with a metamorphosis from polarized to polygonal shapes, a greater abundance of fibronectin and exit

from post-mitotic arrest into the division cycle. Microfilament bundles and feet are therefore not essential for motility and the suggestion is that they set-up cells for anchorage-dependent growth rather than to facilitate movement. This agrees with findings that anchorage-dependent mouse fibroblasts, which had been maintained in suspension, require to re-attach and spread in order to restore DNA synthesis, rRNA synthesis and mRNA production, whereas attachment alone restores only protein synthesis (Ben-Ze'ev *et al. Cell* **21**, 365; 1980).

Observations such as these touch a nerve that runs through much of the fascination with the cytoskeleton: that the way in which it is organized relates to the state of cell growth. It is precisely here that the *src* gene could prove to be an effective probe by disentangling growth control from contact behaviour. This gene of Rous sarcoma virus is responsible for transforming the morphology, motility, metabolism and growth regulation of avian and mammalian cells (Hanafusa in *Comprehensive Virology* **10**, 401, eds Fraenkel-Conrat & Wagner, Plenum, New York; 1977). In order to understand this cluster of responses, it is clearly important to determine the gene product's site of action. That a target for the *src* gene product is the cytoskeleton was suggested by McClain *et al. (Proc. natn. Acad. Sci. U.S.A.* **75**, 2750; 1978) on the basis that dissolution of microfilament bundles occurred within 30 minutes of the microinjection of cytoplasmic extract derived from virus-infected cells. The gene product is now known to be a 60,000 dalton phosphoprotein — a kinase termed pp60<sup>src</sup> which phosphorylates proteins at tyrosine (see Hunter & Sefton *Proc. natn. Acad. Sci. U.S.A.* **77**, 1311; 1980). From its recently determined nucleotide sequence and its association characteristics with plasma membrane preparations (respectively, Czernilofsky *et al. Nature* **287**, 198; 1980; Courtneidge *et al. Proc. natn. Acad.*

*Sci. U.S.A.* **77**, 3783; 1980), it is believed to be embedded in the membrane with its protein kinase activity accessible at the cytoplasmic face. In the light of this, its detection (Rohrschneider *Proc. natn. Acad. Sci. U.S.A.* **77**, 3514; 1980; see Fig. 1) at focal adhesion plaques is highly intriguing since its occurrence there places it at the heart of the adhesion/motility/morphology syndrome. With anti-serum specific to pp60<sup>src</sup>, Rohrschneider detected a speckled pattern of staining on the ventral surface of RSV-transformed rat kidney cells — a pattern which coincided exactly with the distribution of feet (and not with the broader close contacts). The protein kinase was also found in isolated focal adhesion plaques but only from cells infected with the temperature-sensitive mutant when maintained at the permissive temperature; not from cells maintained at the non-permissive temperature at which infected cells appear normal. Since the focal adhesion plaque itself (as distinct from associated microfilament bundles) is formed at both permissive and non-permissive temperatures, it would appear that the protein kinase does not affect foot formation *per se* but perhaps some microfilament-based activity such as their ability to pack into bundles.

A preliminary report provides an interesting postscript to this by suggesting that within adhesion plaques and cell-cell junctions "pp 60<sup>src</sup> was closely associated with actin,  $\alpha$ -actinin and a 130 K protein" (Rohrschneider & Shriver *Eur. J. Cell Biol.* **22**, 521; 1980).

Perhaps further studies on the foot will help nail the persistent idea that cytoskeletal organization and cell growth share something in common. □

Clive Lloyd is in the Biosciences Division, Unilever Research, Bedford, UK.

Fig. 1 Comparison of the same NRK cells by immunofluorescence for pp60<sup>src</sup> (A) and interference reflection microscopy (B) demonstrating that the *src* gene product is localized at focal adhesion plaques.

# AUTUMN BOOKS SUPPLEMENT

## Microprocessors and the printed word

There is now a chance that the coming decade will see the flowering of the revolution in communications that the prophets of technology have foretold since the end of the Second World War. Microprocessors, distributed computer facilities and the like offer powerful ways of storing and handling information. Novel kinds of communications channels promise widespread access, flexibility and low cost. Means of turning electronic representations of information into forms that can be read by human eyes and processed by human nervous systems become more versatile as the years go by. The chances that these devices will be welded fruitfully together in the 1980s are greater than in previous decades. It is, of course, far too soon to be certain how the decade will turn out. A severe and probably prolonged economic recession throughout the industrialized West is hardly the best time for launching a major revolution of technology. Lack of capital may yet frustrate the plans being laid for the new communications technology. Yet it is only prudent that people should be asking what will be the consequences of the promised changes. Already there is a vigorous if somewhat shapeless debate about the consequences for employment: will there be more of it, or less? That argument is likely to grumble on, unresolved, for many years to come. What of more specific questions such as the consequences of the new technology for communication in science and technology? In particular, are the days of the conventional journals numbered?

This is one of the questions raised by a study, now published, carried out by the Primary Communications Research Centre at the University of Leicester. (*New technology and developments in the communication of research during the 1980s*, obtainable from the centre at £2.50 within the UK, £3.00 elsewhere.) For what it is worth, the report of the study appears on ordinary paper. The type has been set by pointing cameras at sheets of typewritten paper. Distribution is conventional, by post. Clearly those who pave the way for revolutions must conduct themselves conventionally for a time, as John the Baptist discovered to his cost.

Indeed, the report of the Leicester group, led by Professor Jack Meadows, is largely a sketch of what the future may bring in the communication of information in science and technology. It is a survey of the options that may open up, not a prescription for a preferred course of development. That, too, is seemly. For in the end, the ways in which scientists communicate with each other will be determined by what they want to do.

It is not, however, too soon to think of what the future may be like. The most radical revolution of the scientific literature rejoices in the name of the "electronic journal". The idea is simple. Somewhere there is a computer system capable of storing scientific articles together with the data, in tabular form, as graphs and photographs. People wishing to submit articles for "publication" merely arrange that the text of their contribution is fed into the system. At some stage, human editors must intervene, if only to decide which scientists in which laboratories should be invited to referee which articles, but from that point the process of publication is more or less mechanical. Referees' comments come and go by the same communications system. Authors are invited to amend their manuscripts, and the revised versions are in due course listed in the public file of articles to which all and sundry may have access. Reading a journal will then be simply a process of pressing an appropriate button on a communications terminal to summon up the latest table of contents and then to display whatever articles may be of particular interest.

This version of the future has a number of attractive features. In principle, it is capable of great flexibility. Some readers of some

electronic journals might wish to read the abstracts of all the articles on the file, and could no doubt be satisfied by pressing a few extra buttons – and for an extra charge. The editors of some journals might decide that articles should be available on the network before they have been refereed, so that readers could share with authors the experience of seeing articles take their final form. Some visionaries even dream of schemes in which the whole of some group of interested specialists would be involved in the assessment of each individual's contributions to the literature. The result might be a much greater sense of community, and that the literature of some field of research is truly the collective understanding and the common heritage of those working in it. Such schemes are by no means as fanciful as they sound. Some of the more interesting of the journals in the conventional scientific literature are those in which each article is accompanied by a string of written comments from others with useful things to say about them.

More modest benefits of electronic journals are probably more nearly within grasp. Plainly, there would be great advantages if the same network could provide its users not merely with versions (printed, or electronic) of articles of interest but also with copies of articles cited in the list of references. The utility of such a system will depend critically on the degree to which the literature as a whole accumulates in electronic form. Searches of the electronic literature for relevant contributions not included in the cited references would also be valuable. Electronic versions of the primary journals could be combined in the same network with more advanced versions of the bibliographic files of titles and abstracts that have made a modest contribution to many people's awareness of the scientific literature in the past decade or so. This, however, is yet another benefit that will accrue only when the process of making the literature electronic has absorbed a substantial part of the whole.

The disadvantages of this way of organizing the scientific literature are, unfortunately, less easily identified. Although it is now customary to suppose that computer technology can be adapted to any task whose specification can be defined, experience has shown that computer systems do not always function as smoothly as their designers hope. The development of computer systems which are acceptable to the users of electronic journals, and not just to their designers and editors, will be slow and expensive. The costs of operating and using electronic journals cannot even be guessed at this early stage. The most obvious difficulty is that the initial costs are certain to be very large. Would-be users will have to equip themselves with communications terminals at a cost that far exceeds the annual subscription to even the most high-priced journals.

Even less tangible disadvantages may be more serious impediments to these developments. Even within the scientific community, people are conservative in their habits. Browsing through the scientific literature, not necessarily in a single narrow field, is not merely pleasurable but educative and stimulating. Will the communications terminals of the future lend themselves to such a practice? But people also appear to like carrying their favourite journals around with them, reading them at home or on some journey. Will a sheaf of hard-copy paper produced by a communications terminal serve the same purpose? People are, in short, attached to the printed word in its familiar form. Those who are now planning electronic journals are no doubt aware of the subtlety of the needs they have to satisfy. Defining them, however, will be a formidable undertaking. Experience may yet show that they cannot be met.

# The ecology of mental process: a life of Gregory Bateson

Edmund Leach

*Gregory Bateson: The Legacy of a Scientist.* By David Lipset. Pp. 360. (Prentice-Hall: 1980.) \$16.95, US only.

Gregory Bateson, 1958

MARGARET Mead died in November 1978, Reo Fortune in November 1979, Gregory Bateson in July 1980. The conjunction of these three most unusual anthropologists in New Guinea at the end of 1932 drastically restructured their private lives. Mead, who was then married to Fortune, was later married to Bateson for 14 years. The consequences for scholarship are still difficult to assess. Fortune ceased altogether to be an effective anthropologist; Mead became an international celebrity, mainly by virtue of highly impressionistic, easy to read, accounts of field research which had already been completed when she first met Bateson. Bateson's principal contribution to anthropology, the awkwardly complex but highly original *Naven* (1936), was also based on fieldwork that had been completed by late 1932, and which was written up in Cambridge before his marriage to Mead. But although it is a very different sort of book from anything that

either Mead or Fortune might have written, it would probably never have been written at all without their stimulus.

In 1936 the dominant style in British anthropology was the extreme empirical functionalism adopted by Malinowski and his pupils, Raymond Firth and Audrey Richards. Bateson, while declaring his respect for the work of this school, also argued that the best ethnography has the artistic merits of a great novel. In his opening pages he invoked the names of Jane Austen and Charles Doughty's *Arabia Deserta*.

*Naven* was an attempt to capture what Bateson called the ethos of Iatmul culture rather than simply to describe, in Malinowskian manner, how everything fitted together. The general attitude to ethnographic evidence which Bateson adopted, which was made to seem quite unnecessarily obscure through his mode of presentation, had much more in common with the later work of Evans-Pritchard and of Lévi-Strauss than it had with then current fashions. But although *Naven* was ridiculed at the time by Malinowski, along with Mead's *Sex and Temperament in Three New Guinea Societies* and Benedict's *Patterns of Culture*, it was a book that was read with great interest by Malinowski's younger pupils, as I can vouch from my experience.

Bateson usually described himself as an anthropologist, but he also had polymathic interests in such fields as animal behaviour, cybernetics and the psychology of schizophrenia. His enduring reputation, which may well prove to be very considerable, is likely to derive as much from these other interstitial activities as from his direct contributions to anthropology.

Lipset's biography, which was published a few weeks before Bateson's death, is a brilliant performance. He had the full collaboration of Bateson himself and of all members of his entourage, including access to family papers and letters, but many of the most interesting passages in the book derive from the personal recollections of those who had known Bateson and whose opinions, as expressed in unstructured interviews, were recorded by Lipset on tape. A great variety of people collaborated in this way, including both Mead and Fortune, and the author has shown astonishing skill and tact in deducing, from what must often have

seemed very contradictory and prejudiced evidence, a balanced account of the life and intellectual development of a man whose persistent curiosity about matters which most of us take for granted sometimes came close to genius.

Bateson's family background was academic Cambridge in high degree. His grandfather, W. H. Bateson, was master of St John's College from 1857 to 1882; his father, William Bateson, was the celebrated zoologist whose renown stemmed from his pugnacious vindication of the genetics of Mendel against the statistical biometrics of Weldon and Pearson. William Bateson invented much of the technical language of modern genetics including the word "genetics" itself. Gregory was clearly greatly influenced by his father; indeed his first publication was a joint-authorship contribution to the *Journal of Genetics* "On certain aberrations of the red-legged partridges . . ." (1926), published when Gregory was 22.

William Bateson, July 1907

But Gregory's intellectual heritage was not restricted to biology. It was William Bateson who first introduced Geoffrey Keynes to the art of William Blake, a field in which Sir Geoffrey, at the age of 93, is

now an acknowledged world authority. This was an enthusiasm which Gregory shared and which is somehow reflected in much of his later work. But probably the most important influences on Bateson's thinking came from his close friend C. H. Waddington, the Edinburgh geneticist. Gregory never adopted the Marxist view of science favoured by Waddington, but he did share many of the latter's humanist concerns. What these concerns were is summed up in the titles of Gregory's last two substantial publications, an essay collection, *Steps to an Ecology of Mind* (1972), and *Mind and Nature: A Necessary Unity* (1979), the latter written at a time when Gregory was fully aware that he was suffering from terminal cancer.

Gregory was not a vitalist; he saw very clearly that the scientific explanation of human behaviour must be of essentially the same kind as the scientific explanation of the behaviour of dolphins. But he was too good a cultural anthropologist to be taken in by the kind of reductionism that is favoured by some of the more simple-minded sociobiologists. The human mind cannot be explained away either as a genetically pre-programmed machine or as an illusory side effect of conditioned reflexes.

Gregory's interests always remained biological; but the focus of his attention was not confined to the human being as a biological organism. It was Man in his social interactions and Man as a species adapted to extremely sophisticated forms of interpersonal communication that provoked his most challenging suggestions. But they were suggestions rather than proven facts. His theories about the nature of schizophrenia and about "the double bind" influenced a wide variety of practising psychotherapists, but they were often misunderstood and they were not of a sort which lend themselves to verification.

Academically he was always a loner; he seldom occupied any position which called for formal teaching. He exercised his influence in private informal seminars and conference discussions and it is difficult to pin down just what that influence was. Gregory was a guru. I know that I myself found him one of the most exciting and inspiring "teachers" I have ever met.

Gregory himself would probably have claimed that his main claim to fame was his application of ideas borrowed from cybernetics to an understanding of the feedback which occurs in person to person interactions. But what he had to say on such matters often contained a good deal of blarney; he had a scientific attitude, but he was not an exact scientist and he was not a mathematician.

Lipset recognizes these limitations. Inspired in his youth by the art of Blake and the laws of Mendel, Gregory aspired to make comparable innovations. He did not succeed, but his contributions to our understanding of the position of mind in

From left: Gregory Bateson, Margaret Mead, Lois Bateson and Barkev Kasarjian

the physical world and to the complex relationships which link form and process are far from negligible.

There is much more to Lipset's book than I have been able to summarize here. The account of the intellectual atmosphere

in which Gregory grew up is particularly impressive. The book as a whole makes a most timely and fitting memorial. □

## Beveridge on discovery

P. B. Medawar

*Seeds of Discovery.* By W.I.B. Beveridge. Pp.130. (Heinemann/W.W. Norton: 1980.) Hardback £6.95, \$12.95; paperback £3.90.

THIS book is a sequel to the author's lively and readable *The Art of Scientific Investigation* (Heinemann, 1957). *Seeds* is readable too — not least because of the wealth of anecdotes and other illustrative material which help the author to make his points; it is a learned man who will learn nothing from Beveridge's pages. Amidst much that is familiar I was very interested to learn that a former Vice President of the National Academy of Sciences had published a demonstration that flight by heavier-than-air machines was not possible.

The present book is not nearly such a success, unfortunately; it is not very original and is in places lamentably trite. Nowhere was I struck, as one always hopes to be, by some felicity of thought or writing. Indeed, I found myself in the disagreeable position of having reason constantly to find fault. As to triteness, consider such a passage as this:

Scientists do not work in isolation. All are members of the world-wide scientific community. It is joined together by

communication through scientific journals and meetings, which are an essential part of science. Formal and informal discussions at scientific meetings, sometimes involving conflict of views and arguments, are a feature of the scientific life.

This is the writing of someone who has nothing very original to say.

The book throughout has a slightly aggrieved and truculent air arising mainly out of the very low opinion Beveridge holds of philosophers of science, whom he accuses of trying to foist on us the notion that scientists operate something that might be called 'the scientific method' — the existence of which, as he rightly says, is a myth. Of the leading philosophers of science, however, it was only Francis Bacon and John Stuart Mill who put before the public an integral body of thought — an organon — that could pass as an exposition of 'the scientific method'. Popper did not, nor did Kuhn. Among Beveridge's many causes of complaint is that philosophers of science have "failed to appreciate the cardinal role that chance and opportunism play in research, and most have dismissed the subject as hardly worthy of their serious consideration".

But what form could such a consideration take? If the story of the remarkable conjunction of events that led to the discovery of penicillin were recounted to a philosopher, what could he say except "Why, gee, what amazing strokes of luck!". If Beveridge himself were a little more philosophical about the matter, he would see that there is an inherent bias in our estimate of the contribution of good fortune to scientific research: we can all recognize when good fortune leads to a discovery or enlarges the understanding, but from the very nature of things we cannot know how often bad luck deprives us of the chance of making a discovery we might otherwise have made.

The most interesting paragraphs in Beveridge's book are those in which he deals with various expedients for promoting the flow of original ideas. Not all are convincing: the more I read and reflect upon the virtues of 'lateral thinking', the more I wonder what all the fuss is about. To be sure, we should all try to be adventurous in our thinking and try to get out of familiar ruts; but this is advice such as Polonius might have given — it cannot come to anyone as a revelation.

Beveridge criticizes Popper, as others have, for failing to throw much light on the process of ideation — the process by which new hypotheses come into being. Popper rebuts this charge perfectly adequately by pointing out that his work is mainly upon the logic of scientific discovery, and that ideation is outside logic and is a logically unscripted process. However Popper is fully aware of the central importance of having ideas as the generative act in scientific enquiry. In spite of Beveridge's criticisms I believe him to be more indebted to Popper than he realizes. In his final chapter, for example, he is clearly feeling his way towards the concept that Popper embodied in the notion of a 'Third World' (Popper's *Third World*; see *Nature* 241, 293; 1973), though Beveridge clothes it in the tiresome terminology of 'hardware' and 'software' — an inappropriate terminology in this context because many ideas and conceptions are embodied in hardware such as machinery, buildings, institutions and so on.

One of the passages in which Beveridge seems to lack philosophic understanding is that in which he deals with frauds. In recounting the Piltown hoax, brought up to date by incorporating Stephen Jay Gould's suggestion that the principal conspirator was none other than Teilhard de Chardin, he says that its main interest is to show "that even the scientific Establishment can be fooled by evidence that in retrospect is seen to be an obvious fake"; but does not Beveridge realize that science, like banking and government and — if that wise man Kenneth Clark is to be believed — civilization itself, rests upon confidence. When we go about our business we do not expect our colleagues and coworkers to be liars; nor do we

scrutinize their statements with wary circumspection, in the manner of men on their guard. If we did so there would be no scientific business to transact. In going on to describe Paul Kammerer's fraud, Beveridge says Kammerer's views on the nature of inheritance were quite incompatible with those of neo-Darwinists "who believed that evolution was due solely to the selection of chance mutations that favour survival". This is a travesty of neo-Darwinism, but it would take too long to explain why.

Accounts of the Summerlin scandal and the fraud implicating Sir Cyril Burt pad out the book readably, but their inclusion may give a rather distorted picture of science to the young scientists who are among those to whom the book is addressed. I surmise — for there can be no proving such a statement — that for every scientist who fiddles his results there are a thousand who do not, and for every scientist who waxes fat on the proceeds of deception a thousand others spend sleepless nights and days of sick anxiety for fear that they have been guilty of a factual misrepresentation — or even, what does not matter nearly so much, of propounding an erroneous hypothesis.

"... most eminent scientists I know do have a lively sense of humour" says Beveridge — a characteristic he chooses to

illustrate by referring to Waddington's witless and disagreeable acronym COWDUNG which stands for 'conventional wisdom of the dominant group'.

Beveridge has some wider views on science in education which I find as difficult to accept as many of those that relate to science itself. He writes that "... it would benefit everybody if the education of scientists included more studies in the humanities ...". I wonder: my own view, as ill-founded as his own, is that the young scientist who has not the initiative and the will to read books or listen to music or visit galleries will be bored out of his mind by lectures of the quality he is likely to receive on subjects such as 'the English novel' or 'the origins of the Romantic movement in Germany'. It would be a different story, of course, if an Ernst Gombrich or Kenneth Clark were to be found on every campus; but what *can* be found on every campus are libraries, radio, television, records and enthusiasts eager to share their enthusiasms — all of which may help to enlarge human sensibilities or human understanding. □

Sir Peter Medawar is Head of the Transplantation Biology Section, Medical Research Council's Clinical Research Centre, Harrow, Middlesex.

## Freudian variations

Stuart Sutherland

*Freud: The Man and the Cause.* By Ronald W. Clark. Pp.652. (Cape/Weidenfeld & Nicolson/Random House: 1980.) £9.95, \$19.95.

Freud was nearly 40 when he began to develop the psychoanalytic ideas for which he is remembered, but even as a youth he was convinced that he would be a famous man. From the age of 21 he periodically tried to destroy all records of his private life in a deliberate attempt to make difficulties for his biographers, each of whom would "be right in his opinion of 'The Development of the Hero'." The latest to take up Freud's challenge is a highly

professional biographer, Ronald Clark, who has already tackled Einstein, J. B. S. Haldane and Bertrand Russell. Fortunately for Clark, Freud's correspondents did not always obey his injunction to destroy his letters and considerable new material has come to light since Ernest Jones wrote the mammoth official biography.

The standard view of Freud's life, as put forward by Jones and other followers, is that he was indeed a hero. They argue that his theories were for long either ignored or derided because of their shocking sexual content, he was denied promotion, he fought with the world in "splendid isolation", and psychoanalysis emerged almost entirely from his own head (or genitals) as a result of his heroic self-analysis. Freud, himself, in his autobiographical writings did everything he could to encourage this view.

In recent years, several scholars have attempted to modify the myth of Freud's heroism. His ideas received considerable support almost from the outset; to the extent to which they were rejected, it was because they were old-fashioned (for example, his attribution of some neuroses to masturbation) or obviously wrong (for example, his belief that many neurotics had been sexually seduced in infancy by an older person). At no time was he isolated from the rest of the scientific community, and many of his ideas were either modifications of existing lines of thought

or were developed in collaboration with others, particularly with Wilhelm Fliess with whom he was in regular correspondence throughout the period when he was developing the basic ideas of psychoanalysis. It is significant that despite their intimacy and the overlap in their work and ideas, Freud does not so much as mention Fliess in his autobiography, and he tried to have his letters to Fliess destroyed. The revisionist view of Freud's career is well summarized by Frank Sulloway in *Freud: Biologist of the Mind* (Deutsch, 1979) which was published too late to be of use to Ronald Clark in writing his own biography.

Clark takes a middle-line on these contentious issues. He concentrates on Freud the man rather than on the intellectual content and origins of his work. On Freud's personality there is little new to say. He was often tetchy and intolerant, as when he reproved his wife for talking to strangers in a restaurant. He could be extraordinarily vindictive: although he formed intimate friendships with several men (such as Breuer and Fliess) the friendships did not last and, once they were broken, Freud never forgave. He loudly proclaimed that psychoanalysis was a science, but he treated it as a religion: he was merciless to the many followers who dared to depart from the orthodox doctrine as laid down by himself. On defection, Morton Prince became "an arrogant ass", Magnus Hirschfeld "a flabby, unappealing fellow", and Carl Jung a "megalomaniac" and a "miserable pen-pusher". One wonders how much insight Freud had into his own childishly defensive reactions.

Another of Freud's persistent traits was that he took great delight in annoying others. Of his fiancée's mother, he wrote "I can foresee more than one opportunity of making myself disagreeable to her and I don't intend to avoid them". He stayed away from one neurological congress because "our absence should annoy them and that suits me". It is likely that Freud's failure to achieve rapid academic promotion was caused more by his own prickly personality than by his Jewishness or the unpopularity of his ideas.

His lust for battle and intellectual arrogance polarized opinion on psychoanalysis. He gave those who were not wholly for him no option but to be against. He made matters worse by his reluctance to admit his own mistakes: for example, he did not publicly disavow his infantile seduction theory until many years after he had himself abandoned it.

In contrast to his behaviour with friends, he seems at least in adulthood always to have been generous and kind towards both his immediate family and his more distant relations. But they would appear never to have crossed his wishes and to have treated him as their natural leader.

Perhaps Freud's greatest virtue was courage. In the last 16 years of his life, he had over 30 operations for cancer of the

Freud and Martha Bernays, photographed in Wandsbeck, her home outside Hamburg, in 1885

mouth and had to wear an uncomfortable prosthesis. He bore the pain and danger with the greatest stoicism, continuing both his writing and his clinical work. When it became clear that he was dying, he calmly asked his doctor to put him out of his suffering. In the face of all medical advice, he went on smoking large cigars to the end of his life.

*Freud: The Man and The Cause* records all this and much more, yet at the end of the book most readers will feel that they have not learned what Freud was really like: his own secrecy about himself and his determination to act the part of hero make it difficult to unravel the inner workings of his mind. Moreover Ronald Clark records events, but passes few judgements of his own.

Perhaps wisely, he neither interprets Freud's life in psychoanalytic terms, nor does he derive Freud's psychoanalytic ideas from his life. The clues to the latter problem are tantalizingly few: Freud had a doting mother; as a young man his attitudes towards the opposite sex were

prudish; his friendships with members of his own sex were highly emotional; and he appears to have given up all sexual activity from the age of 41, by which time he was in the midst of his own self-analysis.

Clark describes the elements of Freud's ideas clearly, but at an elementary level: his excellent index contains no reference to such terms as "displacement", "projection", "regression" or "polymorphous perversity". He makes little attempt to evaluate Freud's work and when he does he is often wildly wrong. For example, he attributes recent revisions of psychoanalytic theory to unspecified advances in biochemistry, and quotes with approval Bertrand Russell's silly criticism of Freud's theory of dreams that "we cannot know what a man dreams, but only what he says he dreams": as far as psychoanalytic theory is concerned, it is irrelevant whether the patient has actually dreamt something or merely thinks he dreamt it.

Clark cannot be altogether blamed for his failure to assess the importance of Freud's ideas. Psychologists still know so

Freud (left) with Wilhelm Fliess, his confidant during the early years of psychoanalysis

little about the forces that motivate human action that the ultimate value of Freudian theory cannot be assessed. It is certain only that much of the theory remains vague and that Freud often overgeneralized: his concentration on the libido and the Oedipus complex as the main influences in the development of personality was mistaken. It is doubtful if present-day psychology would be much different had Freud never lived: his main influence has been on the patterns of thought of the layman and hence on much twentieth-century art and culture. Moreover, there are many who feel that Freud sent psychotherapy in a wrong direction, and that it has only recently

begun to recover from the damage done by his ideas. New therapeutic developments are much closer to Adlerian practice than to Freudian.

There are no pyrotechnics in Ronald Clark's new book, but he has made available in one place a mass of previously published material and has added some facts of his own discovery. Although he has not broken the enigma of Freud's personality, he has produced a highly professional biography. □

## What is it that we know?

D.V. Lindley

*The Enterprise of Knowledge: An Essay on Knowledge, Credal Probability, and Chance.* By Isaac Levi. Pp.462. (MIT Press: 1980.) \$27.50, £17.

A SUBSTANTIAL part of the knowledge of the world that we have today is the result of the activities of scientists. If knowledge is thought of as a tool by which we may control the world, then scientific thinking is pre-eminent. Artists may help our understanding, but it is scientists who develop the techniques and ideas of control. It is therefore surprising that scientists have paid so little attention to the appreciation of how knowledge is acquired and manipulated. Kuhn has pointed out that most scientific work consists of following through a standard set of techniques, or paradigms, and that the individual is so absorbed in the technicalities of the apparatus, the field, or the mathematics, that he never needs to think about the basis of what he is doing. Other scientists, a small but significant minority, do think more widely but again are

typically not concerned with the nature of knowledge. There are exceptions: for example, Medawar's delightful *The Art of the Soluble* (Methuen, 1967) and, perhaps the most important of all, Harold Jeffreys' *Theory of Probability* (Clarendon, 3rd edn 1961).

There are two groups of people who do think about the knowledge business: statisticians and philosophers of science. The former have developed methods of processing data and reaching conclusions that have gained wide acceptance in some branches of science, so much so that it is scarcely possible to publish a paper without the accepted statistical support. Other scientists pour scorn on statistical methods and regard experiments that require statistical analysis as poor experiments: these are the builders of expensive, laboratory equipment. The philosophers have thought and written a lot about scientific method, and have recently considered the statistical techniques as part of that method.

There is one conclusion that all

statisticians and most philosophers now agree upon: the description of our knowledge, and the way that knowledge is used in control, are essentially probabilistic. There are, however, substantial differences on how probability is to be used and what it means. The accepted paradigm of statistics uses probability only in the sense of frequency, so that we may speak of the probability of the experimental results, which may be repeated, but not of the probability of the hypotheses, which cannot. A minority of statisticians, and perhaps the majority of philosophers, think of probability as a direct descriptor of knowledge, so that probabilities of hypotheses are admitted. Some think of this probability as subjective, some as objective. Here philosophy is providing usable, and — it is to be hoped — useful, results; scientists ought to take note.

In this book, Isaac Levi talks of what he chooses to call credal probability as the way of evaluating hypotheses. Knowledge is thought of, not as a collection of results, but as an input to rational decision-making — "Epistemologists ought to care for the improvement of knowledge rather than its pedigree". The same should be true of scientists. Levi is thus no scholar isolated from practice, but a scholar who is concerned with application as the basis of our thinking. (An appendix discusses the use of his ideas in assessing accident risks in nuclear power plants.)

He therefore disagrees with most statisticians' view of probability as only frequentist — in such situations he talks of "chance" — and devotes a fair portion of the book to a criticism of the methods they have developed, paying special attention to Fisher's concept of fiducial probability, a concept that exerts a fascination out of all proportion to its value. His view is the Bayesian one that probability applies to all uncertainty, not just to repeatable phenomena; so that we can speak of the probability of isolated events, or of hypotheses. What Levi calls a "strict" Bayesian, says this probability is unique and definite, and expresses the totality of our knowledge. In conjunction with utility (which receives little discussion in the book) decisions can be made by maximizing expected utility. Levi does not agree with this uniqueness and admits a set of probabilities. This leads to a difficulty, since the existence of many probabilities leads to many expected utilities, and choice between them has to introduce other considerations. He uses a maximin device in which the worst possible outcome is made as attractive as possible. (It is a pity he does not discuss the objections to maximin that exist, especially as he uses a restricted form of that criterion to which they may not apply.)

Levi writes as a philosopher and the emphasis in his treatment is on the ideas rather than their execution. He discusses at length the related ideas of other

philosophers, especially Kyburg and Hacking who have written on probabilistic ideas and is critical of Popper's appreciation of scientific knowledge. And yet his treatment is often realistic, since it is always set against this decision-making, operational background. Thus he criticizes the adherents of the likelihood view, and Shackle in particular, by saying:

The point is, that calling a mode of appraisal a way of measuring or assessing support is not helpful. A specification of the use or function of the mode of appraisal in inquiry and deliberation is needed, whether the method is probabilistic or not.

This is not an easy book to read. It is very long and parts of it are rather technical. For someone concerned with logical questions, his definitions are not as crisp or as clearly laid out as one might wish. There are many parts where the language is turgid; this is his definition of L-irrelevant:

... the information that a trial is of kind T is L-irrelevant to the issue as to whether an R occurs on that trial relative to information that the trial is of kind S if and only if K contains the information that being of kind T is stochastically irrelevant to yielding an R on a trial of kind S.

A more serious point of style that disturbs me is his failure to help the book's readability by adopting standard notation. For example, experts in the probability calculus use  $p(A|B)$  for the probability of A given B. Why then use  $Q(h;e)$ ? And why use irrelevant instead of independent? Much of the later sections of the book are difficult going because of the apparently unnecessary changes of language and notation.

It is a pity that Levi has so little to say

about works of the "strict" Bayesians, de Finetti, Jeffreys, Savage, Ramsey and others. Is he fully aware of the basic result that a man who is to act sensibly can only do so if he acts in accordance with a *unique* probability and a *unique* utility? And why is there no mention of exchangeability, that brilliant notion expounded by de Finetti in his two-volume treatise *Theory of Probability* (Wiley, 1974/5), that connects chance with belief and embraces the frequentist framework within that of knowledge? Levi says in his discussion of nuclear safety, that "the available evidence fails to warrant a sufficiently definite system of credal probability judgments"; but probability is the only description of the available evidence, as Ramsey and others have shown. We may not like the evidence, but probability should not be the scapegoat.

Where does this book stand as a contribution to the study of knowledge? Its importance lies in its new emphasis on a general, credal probability and in its forward-looking, decision-orientated view of knowledge. It leads us further along the road towards a philosophically satisfying, yet usable, appreciation of scientific method: an appreciation that could do much in a really practical way to assist the development of science and technology. And yet, is that not already with us in the work of the "strict" Bayesians? It is to be hoped that scientists will think about these issues, and read de Finetti and Jeffreys as well as Levi. □

## Fit for mankind: a vision of Earth

Paul A. Colinvaux

*The Wooing of Earth.* By René Dubos. Pp.183. (Athlone/Scribner's: 1980.) £7.50, \$8.95.

To woo the Earth means to coax our countryside into the human image of what the good Earth should be. And the image is often very good; a land fair and open, contrived to reflect an ancient savanna where our species was moulded by evolution, long, long ago. We have done this everywhere and the carpers among us are wrong to call our doings bad. This is the Dubos message of good cheer.

Europe is beautiful, with its vistas of villages, pastures and trees. The European wilderness of the old times, where immense, dark forest forever hid the view, was a frightening place. Greece is delightful, even though its shimmering hillsides are only kept bare by relentless overgrazing. New Englanders like their patterns of village and farm, and their

legislators are trying to stop land going back to forest as farms are abandoned. Lovely parklands like the Han dynasty Summer Palace or the creations of Capability Brown are not wilderness but nature contrived to fit the human appetite. Hardly any of us want wilderness. Why not admit this — and be optimistic about how we can change the Earth without ruining it.

Dubos points out that the sainted Thoreau had a comfortable time at Walden Pond, close to the safety of tranquil Concord, and that the sight of a real wilderness of trees in Maine shocked him to hasty retreat. We pay lip service to the wilderness, but most still turn away from its frightening possibilities. We urge Africans to save the game herds, but the Africans will destroy them before the year 2000 because farm land is better than wilderness supporting wild beasts. This seems so self-evident that I have long marvelled at the hopes of those who thought the Serengeti would be saved. We

### Nucleic Acids Synthesis: Applications to Molecular Biology and Genetic Engineering

Proceedings of the International Symposium on Chemical Synthesis of Nucleic Acids. Held May 1980 in Eggestorf, West Germany. Nucleic Acids Symposium Series No. 7.

In the fields of molecular biology and genetic engineering, synthetic nucleic acids and their constituents have proved to be valuable tools and their uses appear to be infinite. In the present era of 'synthetic biology' it is not surprising that the chemical synthesis of nucleic acids is experiencing a tremendous renaissance.

Thus, it was most opportune that this conference, organized by Hubert Köster, should have been held, and the list of participants reads like a 'Who's Who' in the field, together with representatives from industry. This issue of the Nucleic Acids Symposium Series contains details of the latest methods in oligonucleotide synthesis from practically all the leading laboratories in the world, including those of Eastern Europe, Japan and China and serves as a source not only of their current (and usually unpublished) research, but also of their predictions for the future of the methodology and the use of such oligonucleotides.

destroyed our wild animals in Europe and North America, and took their land; we even make newspaper headlines of the escape of a lion from the zoo and public peace comes back only when it is known that the animal is shot. Why should we expect poor farmers of Africa to act differently?

Dubos stresses that they will not, that people do not like wilderness, that we may save some areas as places for adventuring or because it seems sense to keep the gene pools of wilderness species as intact as possible, but that we ought to replace most wilderness with something even better.

Dubos is asserting that there is a silent majority of people who want a friendly, humanized Earth to live on — not danger, not wilderness, not even what is productive or the result of good ecological management, but what is familiar or beautiful. Doubtless he is right, and doubtless the silent majority will have its way. I worry, though, at the tyranny of majorities to those few who, people-like, do not always run with the herd. A real wilderness is marvellous in ways that Thoreau could never feel. A desolate mountain top in the Brooks Range is a better place to be than a man-made space above the English Lakes. To stand, thinking yourself into invisibility in the Amazonian forest, alone and as the hours pass, cannot be equalled in a botanic garden or in the landscapes of a potentate. A proper wooing of Earth will see that she keeps bits of her wild temper intact.

Dubos tries to show that what people like is what they were programmed to like in ancient days when our species was fashioned in some forgotten African savanna. These parts of the book make uncomfortable reading. We are the learning species, the animal who learned to live in almost every habitat of the Earth before we discovered, through agriculture, how to transform our habitats. Yet Dubos sees the Peking Summer Palace as an attempt to recreate the supposed savanna of our species' youth. This has a feel of genetic determinism about it which is not quite nice. The essential thesis of wooing the Earth can stand without this.

Nor does the Dubos thesis need bolstering by ecological theory, yet his is a conservation ethic of sorts and all conservation nowadays argues before the "Court of Ecology". Dubos would have done better not to, for his is still the ecology of the environmental movement with the standard errors.

It is not a fact that ecosystem complexity yields stability. This was a hypothesis of the 1960s, built out of inspired speculating by Robert MacArthur (*Ecology* 36, 533-536; 1955) who drew mathematical analogies between junctions in information networks and species in ecosystems. By the mid-1970s, R.M. May (*Stability and Complexity in Model Ecosystems*; Princeton University Press, 1974), D. Goodman (*Q. Rev. Biol.* 50, 237-266; 1975) and others had shown how unrealistic this

was and many of us ecologists felt grave disquiet years before then. Modern conservationists appealing to ecological Courts really must read up the latest Court Decisions before applying their ecological law.

It is dangerous practice to talk about how ecosystems "evolve"; change they do, but to talk of them "evolving" suggests a mechanism of selection, of the stable replacing the unstable, the productive the unproductive. There are indeed ecologists who seek supra-organismal patterns of evolution like these — but they are not all of the profession and they may not be the wave of the future. Far better to remember that most of the energy flux used to drive an ecosystem is degraded in the non-living portions. In temperate forest some 0.7 per cent of incident solar energy enters the biota through photosynthesis and the other 99.3 per cent is degraded by raising temperatures or evaporating water (H. Lieth and R. H. Whittaker, *Primary Productivity of the Biosphere*; Springer-Verlag, 1975).

The biota adapt to this energetic reality much more than they control it. Progress towards a nebulous "climax" is a shuffling in line before the energy soup-kitchen, until everyone has found a place of sorts and there is a quasi peace. Incidentally, this is why our human systems have, in general, worked so well; we have altered the arrangement in the biological energy queue without tampering with the main patterns of energy flux. It is only when we do

something terrible to the landscape, such as promoting soil erosion or building a dam, that major diversions in primary energy flux reflect true system instability.

Dubos has a wise and sane vision — an Earth kept diverse and pleasant for human use, made richer by human invention than wild nature had left it. Leave some wilderness for some of us to spend a few hours in and change the rest, ever so gently, until it is good. Yet he protests how well he understands that all will be vain if our numbers keep on growing and that much will be imperilled if we go to nuclear war. But on the ecological subject of human numbers he has nothing to say. He believes that the remorseless rise of population has something to do with curbs in the death rate made by the medical profession and he savours the hope that our numbers may be levelling off. These are views not tenable in ecological logic. Numbers rise because the human breeding strategy remains that of achieving optimum clutch and the destructions Dubos fears will come about as we seek to find adequate niche-space for the surplus individuals that result (P.A. Colinvaux *Nature* 26, 256-357; 1976. *The Fates of Nations*; Simon and Schuster).

Yet it is good to read honest statements that all things done by mankind to the environment are not bad; indeed that most things done have had satisfactory results.

Paul Colinvaux is a Professor in the Department of Zoology at The Ohio State University.

## Survival of the fittest author

Wilma George

*A Delicate Arrangement: The Strange Case of Charles Darwin and Alfred Russel Wallace.* By Arnold C. Brackman. Pp. 370. (Times Books: 1980.) \$12.50.

THIS is a disappointing book. It promises to uncover a plot but fails to convince and fills up pages with incomplete biography. Many people would agree with the author that Alfred Russel Wallace had less than his fair share of publicity but few would agree with his interpretation that Darwin cheated Wallace and that Lyell and Hooker connived at the plot.

Brackman rests his case on dates: the supposed date that Wallace sent his natural selection paper to Darwin and the supposed date that Darwin received it. Wallace thought he sent it in March 1858 and Darwin thought he received it on 18 June but Wallace's envelope with its postmark has not survived. Brackman claims that because Wallace posted a letter to F. Bates on 9 March which arrived on 3 June he must have posted his article to Darwin on the same date and, therefore, the article must have arrived on 3 June.

This is not evidence. This same "evidence" has been used by H. Lewis McKinney in *Wallace and Natural Selection* (Yale University Press, 1972) to claim that Wallace cheated (to say he was where he was not).

Brackman claims that Darwin cheated by saying he had received Wallace's article on 18 June (and not 3 June) in order to quarry it for data and ideas before writing to Lyell. The "evidence" is supported by the fact that Darwin did not keep letters during the 1850s — and that Wallace was a member of the lower classes.

Brackman implies that Charles Darwin or his son Francis destroyed letters because Wallace was writing to Darwin about his ideas on species. But Darwin did not keep letters systematically until he became famous. Brackman also implies that Darwin was surreptitiously using Wallace's 1855 paper on species when the 1855 paper was in print!

Brackman's narrative style is "surreptitious", to say the least: "A troubled Darwin opened Wallace's letter". In fact, it is downright dishonest: "For Darwin his success in securing Wallace a

Wallace, aged 30 . . .

. . . and at 46.

measure of security for the remainder of his natural life was an act of expiation". It is a dramatic language: "Darwin understandably panicked". And the reader might understandably panic, too: "Both letters exhibit guile, glibness, and guilt mixed with integrity and honor".

Darwin was distressed when Wallace's 1858 article reached him but distress does not prove guilt. There is no evidence that Darwin plundered Wallace's paper for ideas and wrote them into his own manuscript. Darwin had been brooding on his theory for years and had not written his book and I find his outcry about loss of priority entirely natural. Darwin did not seize on Wallace's idea of divergence and make it his own in the supposed two-week interval between receipt and admission of receipt of Wallace's 1858 article. In 1855, Wallace had written in a paper appearing in the *Annals and Magazine of Natural History* (16, 184-196): "But if two or more species have been independently formed

. . . then the series of affinities will be compound and can only be represented by a forked or many branched line". As for the mechanism, Darwin had written to Asa Gray in 1857 (and the letter is not a fake) of: "an unerring power at work in *natural selection* (the title of my book)" and of a principle of divergence "which shows that organic beings seem to branch out into all the places available".

I find no case against Darwin. I think that the explanation for Wallace's partial eclipse from the evolution-by-natural-selection debate is less dramatic. Darwin's fame came not from the appreciation of a new biological theory by a few members of the Linnean Society but from the intelligent reading public. Evolution by natural selection was a revolutionary theory but the public of Victorian England did not read the proceedings of the Linnean Society. It read books. And the readers, shattered by the convincing mechanism for a process which was already a subject of conversation, were troubled by the implications of the theory for the status of man.

Wallace did not write an *Origin* (it was Darwin who provided a detailed account of the process of organic evolution which was accessible to the reading public) and Wallace developed unacceptable ideas about the evolution of man. Finally, Wallace, the younger man by 14 years, insisted that their theory should be called Darwinism, summing up the situation himself when he wrote to Darwin in 1864:

## Animal arms races

John R. Krebs

*Tooth and Claw: Defensive Strategies in the Animal World.* By J. L. Cloudsley-Thompson. Pp.252. (Dent/Biblio: 1980.) £9.95, \$22.50.

THIS is a popular book about the ways in which animals defend themselves against predators and the counter-adaptations of predators to overcome their prey. It covers similar ground to *Defence in Animals* by M. Edmunds (Longmans, 1974) and *The Ethology of Predation* by E. Curio (Springer-Verlag, 1976), but is aimed at a more general audience.

Most of the text consists of examples, many based on the author's own observations of different kinds of anti-predator adaptation and tricks used by predators to catch their prey. Examples of camouflage, mimicry, venoms, defensive spines, armour and so on are described in a charming and entertaining way. Most readers are certain to come away with at least one or two good coffee-time stories. My favourite is about the African water mongoose, which is alleged to catch birds by sticking its rear end in the air and distending its anus to make it look like a

You had worked it out in details I had never thought of, years before I had a ray of light on the subject, and my paper would never have convinced anybody or been noticed as more than an ingenious speculation, whereas your book has revolutionised the study of natural history.

But I am glad to see a book that publicizes Wallace's contribution to the theory of evolution by natural selection, a book that reprints both the 1855 and 1858 species papers — though it is a pity that Darwin's 1858 contributions were not included for the reader to make his own judgement — and a book that has some hilariously scabrous comments in the "Author's Notes". Wallace's name is heard today much more often than it was in the nineteenth century, partly because of the lessened obsession with the evolution of man and the increased interest in other implications of the theory, partly owing to the work of the historians of science and partly because of the return to fashion of evolutionary zoogeography founded by Wallace and stamped indelibly with his "line". But the more Wallace is linked with Darwin as a co-founder of the theory of evolution by natural selection, the more will historical accuracy be served. Thus, even a negative book like this contributes to the subject. □

*Wilma George is a Lecturer in Zoology at the University of Oxford, and the author of Biologist Philosopher: a Study of the Life and Writings of Alfred Russel Wallace (Abelard-Schuman, 1964).*

ripe fruit. Along comes an unsuspecting bird to peck at the fruit and with a smart about turn the wily mongoose snaps it up! Second place goes to the story about frogs' legs and the genitalia of French soldiers in nineteenth century Algeria (without giving too much away, the British are right to stick to pie and chips), and a close third is the account of how large tropical scolopendromorph and scutigermorph centipedes escape from attackers. When attacked or frightened, they shed one of their back legs; the automatized leg leaps around making loud creaking or stridulating sounds to attract the attention of the predator while the nonagintanovipede slips silently away.

Cloudsley-Thompson also tries to extract some general principles about coevolution of predators and prey. He draws a parallel between military arms races and the coevolutionary race between predators and prey. In both military and coevolutionary races, adaptations or innovations by one party call forth counter-adaptations by the other. These counter-adaptations lead in turn to counter-counter-adaptations and so on. One general principle applicable to both kinds of race is the concept of a "trade off" between competing demands. Heavy armour may render a tank less vulnerable

to shell fire, but at the same time it reduces speed and mobility. In the same way animal defences may work well against one kind of attacker but be much less effective against others. The king cobra, for example, is venomous enough to kill an elephant, but is itself killed on occasions by the mongoose with its superior agility.

A closely related idea is that every defensive adaptation has a "cost" which might, for example, be measured in terms of energy that could otherwise be channelled into reproduction. One of the most convincing pieces of evidence for the cost of anti-predator adaptations comes

from the study of chemical defences in plants (and is therefore not discussed by Cloudsley-Thompson). R. G. Cates (*Ecology* 56, 391-400; 1975) has shown that wild ginger plants (*Asarum caudatum*) in places where slugs are common channel more energy into chemical defence (they taste nastier) at the expense of seed production and growth than do plants of the same species where there is little grazing pressure.

The book touches on some issues without trying to discuss them in their full complexity. For example, in the discussion of Müllerian mimicry (mimicry in which several unpalatable species share the same colour patterns) Cloudsley-Thompson presents the conventional argument that a shared colour pattern reduces the chances that an individual will be killed by a predator in the process of learning to associate colour with distastefulness; the larger the pool of similarly coloured prey

individuals, the smaller the chance that any one of them will be killed. While this argument seems to be correct, it leads one to expect that all unpalatable species living in the same habitat should share the same warning colour patterns. In fact it is known that neotropical butterflies, for example, form several different Müllerian mimicry complexes within the same habitat (C. Papageorgis *Am. Sci.* 73, 522-53; 1975).

The mechanism of evolution of warning coloration is also glossed over, with no mention of R. A. Fisher's suggestion that it might have arisen through kin selection.

However it would be churlish to criticize a popular book for not exploring recondite details. The main aim of Cloudsley-Thompson's book is to entertain and stimulate the reader. In this it succeeds. □

John R. Krebs is a Lecturer in the Edward Grey Institute of Field Ornithology, Department of Zoology, University of Oxford.

Chemical defence: when disturbed, *Eleodes* sprays a secretion at the attacker from its abdomen.

## Animals for the coffee table and student

Bryan Turner

*The Complete Encyclopedia of the Animal World*. Edited by David M. Burn. Pp. 400. (Octopus: 1980.) £12.95, \$17.98.

THE diversity of animals, the sheer numbers of species, and the richness of their differing forms and functions has always fascinated people. It attracts the curious layman and for biologists begs answers to questions of "how?" and "why?". Although this book has been written and designed to adorn the coffee tables of the general public, students of zoology will find much to interest them. The book is of a higher intellectual standard than that customarily associated with this sort of glossy volume, in part due to the impressive list of contributors. Each section has been written by an acknowledged expert in that particular field. Skilful editing has successfully combined the many and varied styles of the contributors in a way that makes section to section differences unobtrusive.

The text is complemented by a beautiful series of colour photographs and novel illustrations. Although most of the illustrations are useful, some are confusing; for instance, in a figure of the distribution of the geological plates of the Earth's crust the key is absent so that the variously coloured boundaries are meaningless. Perhaps somewhat more important than minor irritants of this nature is the discussion on the links between the chordates and the non-chordates (essentially but not precisely equivalent to the vertebrates and invertebrates). Here the widely held ideas of a link involving the hemichordate acorn worms are dismissed and a new but little accepted theory involving the fossil calcichordates is

expounded. In a general text such as this the most widely accepted views of the experts should surely take precedence, and any new and highly controversial ideas take second place.

The main part of the book is a catalogue of the different groups of animals which is sandwiched between chapters on special aspects of animal life. There are introductory chapters on ecology, in which the biologists' "how?" and "why?" questions are briefly considered, and on taxonomy explaining the classificatory process. This latter section is introduced by a full colour photograph of the book's editor in the guise of a lepidopteran taxonomist supposedly illustrating the qualities of "Patience, experience and a good eye" — perhaps a book on brass instruments will be next! Other specialist chapters include such topics as locomotion, migration, senses, associations, endangered species and a useful section on the major zoos and national parks of the world. The foreword, curiously by David Bellamy, the "Botanic Man", is accompanied by a picture of him riding a tortoise. To ensure that we recognize him, the usually sufficient facial characteristics have been supplemented by those other well-aided taxonomic features — the hairy legs!

These asides apart, this book does represent a good, balanced and informative account of the immense variety of animal life. Although unable in 400 pages to live up to its title "Complete", it is none the less a very creditable contribution from the Octopus stables. □

Bryan Turner is a Lecturer in Zoology at King's College, London.

# The blooming of a hobby: a history of natural history

Alwyne Wheeler

*The Heyday of Natural History.* By Lynn Barber. Pp.320. (Cape/Doubleday: 1980.) £9.50, \$17.95.

THE middle years of the nineteenth century saw a striking flowering of popular interest in natural history in Britain. The economic and social conditions of the time had produced an increase in the number of literate people who had more leisure and were thus able to utilize their time in what was clearly a health-giving, mind-improving hobby — both worthy objectives in the moral climate of the period. In addition, developments in printing, for example stereotyping and electrotyping, permitted a great increase in the number of popular books, often illustrated with colour plates at relatively low prices.

The result was an extraordinary burgeoning of the literature of natural history written for a popular market. The availability of such books stimulated the interest of even more middle-class naturalists, to result in a cycle of demand and supply which saw the nineteenth century out. The consequences of this great increase in popular natural history and its literature have had considerable influence in our time, for it was during the mid-nineteenth century that many local natural history societies were founded (and those that came later were started by people raised during the period). Many such societies started local natural history museums, and even now have their own publications and libraries, and thus still exert a considerable influence on natural history in Britain although, responding to pressures on the environment today, much of the amateur naturalist's efforts go in supporting conservation-orientated societies.

In this view I differ from the conclusion of Lynn Barber that from the 1870s, in the aftermath of the revolution in thought following the acceptance of Darwin's theories, natural history became "dull". The later years of the nineteenth century simply saw a dichotomy between amateur naturalists and professionals, the latter having been few in number before the 1870s. The amateur interest in natural history has continued as strongly as ever, but the professional naturalists have become more specialized in their fields and in their writings, and few have possessed the breadth of knowledge, the ability or the bravery to produce popular writing comparable to that which flourished in the Victorian period.

Lynn Barber's book is a most readable account of the great years of the Victorian naturalists (Victorian being loosely applied). The story is a good one, some

"Scientific Conversazione at Apothecaries' Hall", from the *Illustrated London News*, 1855

"Holiday Time at the Zoo", 1872

The Iguanodon dinner, 1854

superbly interesting characters appear and the material is handled in a masterly fashion.

The first section recounts the social and historical backgrounds, the second contains accounts of Linnaeus, Cuvier, Audubon, Rafinesque, Swainson and Charles Kingsley. Later sections feature Waterton, Gosse, Ward, Mary Anning, the Bucklands, Owen, Sedgewick, Murchison, Huxley and Darwin. But the treatment is not merely biographical; rather, the work and the influence of these "giants" of the nineteenth century is skilfully woven into an account of the development of British natural history, although biographical details have been included to set them in their background. In working this complicated tapestry into an attractively presented, enjoyable and well-written story Lynn Barber deserves all credit.

No doubt it is because of her background as an experienced journalist and broadcaster that her book is presented with such panache. This background may, however, have led her to include some "human interest" stories which are generally now discredited amongst historians of natural history. Thus, the loss of labels from Cuming's mollusc shell collection due to Mrs Gray's carelessness is now dismissed as a canard. Nor was the unfortunate A.W.E. O'Shaughnessy's appointment in the British Museum to work on insects due solely to the influence of his patron as is inferred here; he was simply transferred from one department within the Museum to another, having passed a test of his knowledge of zoology which the other contender had failed.

One has to say that most of the sources used by Miss Barber are secondary. I doubt whether one can rely overmuch on Kingsley's view of Victorian natural history, or on William Swainson and especially not on Audubon for objective

Frank Buckland, naturalist extraordinary

views of their contemporaries. They were all too involved in the period themselves, and Swainson and Audubon certainly had axes of various kinds to grind. The reliance on secondary sources tends to affect the overall images in the book, and also possibly accounts for some of the more alarming generalizations and particular errors. Surely it is not true that between Cuvier's *Le Règne Animal* of 1817 and Darwin's *Origin of Species* in 1859 "almost no major breakthroughs were made"? Two discoveries alone, that of Schwann (1839) of animal cells, and that of the mammalian ovum by von Baer (1827), would today be given the accolade of "breakthroughs".

For these and other reasons Lynn Barber's book cannot be credited as an original history of natural history, but as a readable and well-produced introduction to the subject it is unsurpassed. □

*Alwyne Wheeler is editor of the Archives of Natural History (formerly the Journal of the Society for the Bibliography of Natural History) and works at the British Museum (Natural History).*

## The "why" of animal culture

W.C. McGrew

*The Evolution of Culture in Animals.* By John Tyler Bonner. Pp.216. (Princeton University Press: 1980.) £8.10, \$14.50.

A DISTINGUISHED cell biologist, J.T. Bonner, has written an ambitious book on the behaviour of animals. In it, he tackles the question of culture as a direct product of the evolutionary processes of natural selection: "[Culture] . . . is as biological as any other function of the organism, for instance, respiration or locomotion". In addressing social scientists, Bonner does not shrink from the implications of this position for human culture and confronts the issues in his opening chapter. From the beginning it is a pleasure to find a book so lucidly written and so free of jargon.

The author's ultimate goal is to explain why we (humans) have culture at all. To

appreciate its adaptive significance requires a step-wise reconstruction of its phylogeny, and it is to this task that much of the book is directed. Bonner starts at the most basic levels of evolutionary mechanisms and advances on a broad front. His definitions are as comprehensive as possible; culture is defined as "... the transfer of information by behavioural means, most particularly by the process of teaching and learning". (Such a definition is not without faults, for instance it gives no inkling of the cumulative nature of the phenomenon). The author compares the genome and the brain as information-processing structures, with genes and "memes", respectively, as the units of information transmission — here, and elsewhere in the book, he calls upon Dawkins's *The Selfish Gene*. The latter

system is speedier and more flexible, but it is ultimately limited by the former. The emergence of large brains in human evolution is credited to neoteny, that is, the retention of juvenile traits whereby the brain goes on growing in size after the growth of the rest of the body has slowed or ceased.

Having laid the structural groundwork, Bonner turns to the most basic behaviours. A long chapter on animal societies (which draws heavily on Wilson's *Sociobiology*) relies on the premise that culture requires communication, which is most developed in social organisms. Here, and throughout the book, Bonner chooses to start with microorganisms and work his way through progressively more complex multicellular forms. An excellent discussion of genetic flexibility is followed by the introduction of the concept of a dichotomy of behavioural flexibility: single-response behaviour versus multiple-choice behaviour; this appears to be "nature versus nurture" re-labelled.

The real problems begin to arise with the author's treatment of learning and teaching. All social learning seems to be classified as imitation, with no distinction being made between types requiring differing degrees of mental ability — mynah birds and human infants may both learn English, but the learning of the bird is merely mindless mimicry. No mention is made of "mixed" forms, for example observational learning by a combination of stimulus enhancement (social) and trial-and-error learning (non-social). Finally, there is no reference to behaviours which involve communication but not (necessarily) learning, social facilitation of pecking in domestic chicks, for example. Crucial to the author's argument is teaching, which he defines as "... the release of sets of signals specifically designed to alter the behaviour of another individual". This presents a rare example of ambiguity: in a general sense such a definition applies to all communication; in a more specific sense, it leaves open the question of whether or not intentionality (or goal-directedness) is involved. The reader is told that a large share of teaching

by higher vertebrates can be considered as parental guidance, and that a parent will shape its offspring's imitative performance with nudges, pokes and slaps. But, apart from a single anecdote, no evidence of this sort of behaviour is presented. Contrary to the author's conclusion, it seems likely that it is just this sort of teaching which is conspicuously absent in non-human animals.

The book builds toward a synthetic final chapter which I found somewhat bewildering. Norton-Griffiths's exemplary work on the intergenerational transmission of feeding techniques in oyster-catchers is given suitable credit, but a number of other, equally significant studies are not mentioned. The "natural experimental" research into cultural innovation and diffusion in Japanese monkeys rates only one paragraph; an admittedly fascinating anecdote of one-trial, avoidance learning by elephants is given preference to the many studies of culture in non-human primates — Menzel's volume on the subject is ignored; fidelity to nesting sites in migratory birds is emphasized, in spite of the fact that no social learning need be posited, just as it is not invoked to explain the homing of Pacific salmon to spawn; even the memorable example of milk-bottle opening by tits merits only three sentences. Finally, the section on human culture cites no specific examples, and some of its general conclusions will cause disquiet amongst the social scientist for whom the book is intended; for example, the author's linking of the rise of culture to the rise of writing seemingly bars extant pre-literate societies from consideration.

Yet, overall, in this book Bonner has produced a clear, compelling and wide-ranging account of the bases for social communication in animals. However, those more interested in the evolutionary mechanisms of transition from non-human to human culture are left wanting. That particular book remains to be written. □

## Rural nostalgia

Kenneth Mellanby

*Hampshire Days.* By W.H. Hudson. Pp.250. (Oxford University Press: 1980.) £1.95.

COUNTRY lovers will be grateful to Oxford University Press for reissuing this book in such an attractive paperback edition some 80 years after its first publication. W.H. Hudson was a naturalist who observed the countryside and its wildlife wherever he was, in South America or rural England.

His publishers describe him as "a passionate observer of nature", and this is what emerges from his prose. He gives us accurate and perceptive accounts of the plants, insects, mammals and particularly the birds seen in his garden and in the Hampshire countryside. Some scientists may find his description of his feelings, and his attribution of human emotions to birds and even insects, alien to their tastes, but they will soon be brought back to earth by his unsentimental and accurate accounts of life and death in the countryside.

Hudson's love of rural life was mirrored by his hatred for urban living. He disliked

the townsmen, with "their pale civilized faces — they are out of my world — the real world". His passion was for "wildness — the rude heath, the beautiful desolation; furze and ling and bramble and bracken to grow on me, and only wild creatures for visitors and company". He was of course aware that he was observing not the natural face of England, but the result of the interplay of human activities and ecological processes. He describes prehistoric barrows as well as traditional farmhouse and agricultural activities. But at the time he was writing it was possible to imagine that there was a harmony between man and nature which resulted in the beautiful landscape he so vividly describes.

How he would have hated the changes which have taken place in his beloved Hampshire in recent years. Many of the woods and heaths have gone, some of the hedges have been ripped out. Men are even prospecting for oil! Modern farming is very different from that of his day. Yet a great deal remains. We can, if we are lucky, still see most of the sights he so graphically describes. But few of us have his "seeing eye", and in a lifetime of study may not make all the observations his skill and his sympathy made possible in a few brief years at the beginning of this century. □

# Retrospective environmental impact assessment

Eric Ashby

*The Volta River Project.* By David Hart. Pp.131. (Edinburgh/Columbia University Press: 1980.) £7.50, \$20.

MEMBER states of the European Community will shortly be asked to adopt a common policy for environmental impact assessment. The individual members already have policies of their own; so the wrangling — and there will be plenty of it — will be about the means for predicting environmental impact rather than whether to do it at all. The ends are clear: to reconcile the inevitable conflict between exploitation of nature for the benefit of Man, and conservation of nature also for the benefit of Man. The wrangling begins when you ask: for whose benefit and at whose cost? And the conflict is confused because we do not know how to predict and we cannot agree about who should participate in assessing predictions.

In Britain the current procedure is to hold ministerial enquiries, commonly under the Town and Country Planning Acts. No one pretends that they are satisfactory (think of the bitterness left after the enquiries at Windscale about fuel reprocessing and at Winchester about the route for a motorway); but even critics of the British procedure prefer it to the bureaucratic hypertrophy of the Environmental Protection Agency in the United States. The trouble is that no one seems to be thinking about the problem in a scholarly way, that is, by examining past experience and trying to draw lessons from it. What we need, before we commit ourselves to European policies for environmental impact assessment, are *retrospective* studies of technology assessment and environmental impact predictions. Academics have done a little work, notably Roy Gregory in his book *The Price of Amenity* (Macmillan, 1971), and a team sponsored by the American Academy of Arts and Sciences in their study *Boundaries of Analysis* (Ballinger, 1976). But much more work needs to be done. That is why this modest study of the Volta River project in Ghana deserves careful reading. We may think we manage environmental affairs better in Westminster than they are managed in Accra, but Ghana has something to teach us, even though it is a cautionary tale.

Among people unfamiliar with West Africa there is still a residual euphoria about the great Volta River project. Isn't it exactly what Third World nations need: to enrich themselves by generating energy, creating industries, raising living standards? The message in David Hart's book is that the Volta River project was not what Ghana needed — at any rate not what the great majority of the people of Ghana needed or ever asked for. It was wished on

Ghana by the West: Britain wanted an assured supply of aluminium from the sterling area; the Kaiser Corporation wanted a large supply of electricity with which to produce cheap aluminium. So under the pure white banner of 'aid' the West descended on Ghana, created a lake which occupies 3.6% of its land-area and dispossessed some 1% of its population. (A rough analogue for England would be to flood the whole of Devonshire and to decant its 460,000 inhabitants into other parts of the country.)

The Volta River project was contemplated as long ago as 1915 by the man who was at that time director of the Gold Coast Geological Survey. The idea was revived about 1948. A special commissioner, Commander Jackson, was appointed in 1953 to report on the whole project and its implications, without prior approval from the legislative assembly in Accra (a sign, as Hart says, "that the real decisions were being made elsewhere"). Even at that stage two influential and distinguished members of the assembly, Danquah and Busia, voiced their doubts. The primary purpose of the Volta River project, they said, was the production of cheap electricity to smelt aluminium; the development of Ghana was only a secondary purpose; the people of Ghana would benefit more from a smaller project to supply electricity to many towns, and to provide irrigation.

And so it has proved to be: aluminium is being smelted, but it has not brought the benefits to Ghana that were promised, and its destiny is in the hands, not of the Ghana government, but of the International Primary Aluminium Institute. As to the benefits to Ghana, Hart's account of the plans which were made to re-settle the 80,000 people occupying 739 villages in the

area to be flooded is a sardonic comment on the incompetence of planners when they have to deal with the human consequences of their decisions. Of course there were plans to compensate the people ejected from their holdings and to give them land elsewhere. In the event the plans were so mismanaged that much of the compensation is not paid, even today, and much of the re-settlement has proved abortive. Polygamous extended families, accustomed to having separate houses, however simple, for their wives and relatives, were given a house suitable only for a nuclear family. In their new locations the pattern of their society, the markets — the familiar locations for buying, selling and making social contracts — vanished; even the styles of agriculture and fishing had to be different. From a world of poverty ameliorated by security they were shovelled into a world of poverty exacerbated by stress. There were tensions among the indigenous occupants of the lands where the re-settlements took place. There were scandalous under-valuations of the property some of them had been obliged to abandon. And, on top of all this, there were alarming increases in the incidence of bilharzia, owing to the opportunities for the snail which transmits the disease to breed in the still waters of the lake; Hart publishes a map of the lake showing places where 70–100% of people sampled were infected.

I said that the experience in Ghana may have lessons for Britain; a remark which will provoke the protest: "It couldn't happen here". Not in the same way, it couldn't. But when we plan airports, motorways, power stations, what proportion of cash, thought and effort is put into the second-order effects of the pro-

The Volta dam — what benefits has it brought to Ghana?

jects? And are the decisions as to what is 'good' for the local populace made locally, or in London? (One perceptive comment on the environmental impact assessment made for the Volta project was that it was made by Westerners for Westerners; what was needed was a team of 'barefoot anthropologists' to live among the people affected by the Volta dam, and then to recommend how they should be handled.) If the people who say "it couldn't happen here" will pause a moment, they may recall the preposterous tragedy of taking people out of down-at-heel terrace houses and hoisting them up into high rise flats; or resettling people from the cohesive and compassionate society of a slum into neat, clean, aseptic villas in a suburb.

Upheavals in our traditional ways of life are inevitable; we are in for a lot more of them; people will have to migrate from the closed steelmills of Corby as surely as they

had to migrate from the waters of the Volta River. The British people are flexible and courageous enough to tolerate these upheavals. What they will not — and should not — tolerate is the pained surprise of planners when some of the remedies proposed from Whitehall are rejected. The way to minimize mistakes — they can't be avoided altogether — is to improve the standard of environmental impact assessment; and the way to do that is to study very carefully case-histories of past assessments, to diagnose where they went wrong and what they left out. David Hart's little book, despite its high price, ought to be on the bookshelves of planners; for he does what he sets out to do: he gives a case-study of politics and technology relevant not only to Ghana but to Britain. □

## Questions of energy

Joseph S. Nye

*World Energy Issues and Policies.* Edited by Robert Mabro. Pp.367. (Oxford University Press: 1980.) £15, \$44.50.

THIS volume is a collection of papers from the first Oxford Energy Conference, held at St Catherine's College in September 1979, and cosponsored by the Organization of Petroleum Exporting Countries and the Organization of Arab Petroleum Exporting Countries. The Secretaries-General of the two organizations provide two of the 28 papers in the book. Distinguished OPEC contributors also include Kuwait's Minister of Oil and Venezuela's Minister of Energy and Mines. Other essays are contributed by government, industry and academic figures from various oil-consuming and -producing nations. A brief introduction and summary is provided by the editor, Robert Mabro.

As might be expected in a diverse collection of conference papers, there is great unevenness of quality and style. Mabro explains that the essays have "not been heavily edited" in order to avoid lag in publication and to preserve their flavour of authoritative statements. Fair enough, though the disparities on occasion jar somewhat — a brief section, "World Energy Outlook", pairs Wolf Hafele's 23 pages on world regional energy modelling over 50 years with three pages of casual observations by the late C.C. Pocock of Shell Oil.

A more important problem is the gaps in coverage. The resulting tone of the book certainly leans toward the energy establishment. The editor acknowledges some omissions and wishes he had an environmentally orientated paper to balance the

chapter on nuclear energy written by an industry representative. He also regrets the absence of a contribution from a senior official of a major OECD country such as the United States, but explains that official speakers at the seminar were encouraged to speak off the record. A rule that may have been good for the conference, however, is not good for a book. The result is a meagre two chapters, one on the United States by an academic and one on the United Kingdom by a deputy undersecretary of energy, in the section on energy issues and policies of OECD countries. In contrast, there are six papers (including by highly placed OPEC officials) in the section on energy issues and policies of oil-exporting countries. Moreover, the paper on United States' policy entitled "A Critical Overview", hardly purports to be a balanced presentation.

Despite the problems of unevenness and gaps, there are several useful papers in the volume, especially in the opening section on energy supply. Particularly interesting is the paired treatment of natural gas by Nordine Ait-Laoussine of Algeria and James Jensen of the United States. On the other hand, one would have thought coal deserved more than five brief pages. There are descriptive discussions of the Soviet Union and China by Michael Kaser and John Foster, and many of the papers by officials are of interest not because of their analytical insights, but because of their author's positions. If treated as a smorgasbord, the book succeeds in one of the editor's purposes in that it does present some interesting conference fare for a wider audience to sample.

Mabro also has an explicit political objective: "to improve the chances of

success of any future formal dialogue which Governments sooner or later will have to initiate". In his summary, Mabro says that "the urgent need for dialogue was almost unanimously recognized", but there was little agreement on modalities or scope of the agenda.

The idea of a dialogue between OPEC and consumers is currently fashionable in the aftermath of the Brandt Commission Report. A consumer-producer dialogue might help nations shift their focus to the potential long-term joint benefits to be gained. Such a dialogue might seek inter-governmental agreements to stabilize the oil market; for example, OPEC and IEA countries might agree on production targets and consumption limits (at first separately, and then in joint bargaining) which would allow for modest real price rises over the next decade. A band of prices might be established for the duration of the agreement. OPEC countries would agree to maintain sufficient spare capacity to increase production if a shortfall of production from any subgroup of producers threatened to push prices outside the band. They would cut production (or agree to permit consumers to increase demand above the agreed limits) if prices threatened to fall through the bottom of the band. Additional inducements might be needed to assure adequate production levels. For example, consumers might offer indexing of assets and assurances of assistance and market access for the new OPEC industries. Special credit or aid provisions might be agreed for oil-importing developing countries; some such countries could be included in bargaining sessions.

But a number of hard questions must be answered. Could the agenda be focused on energy? If other developing countries participate, will the world replay sterile North-South debates, but with much higher stakes than in the United Nations? Can the "Pandora's Box Effect" be controlled if nations start down the path to serious international collective bargaining?

Is a reasonable bargain likely? At modest prices there are divergent interests between those OPEC surplus producers who lean toward conservation and the high-absorbers interested in maximizing revenues. Large price increases (which maximize revenues and allow painless production cutbacks) tend to reconcile that division. Would OPEC countries be able to agree to a bargain that meant higher production and lower prices than the market would otherwise determine?

Does OPEC have sufficient cohesion to make a bargain stick? Thus far, OPEC countries have been unwilling to limit their separate sovereign control over production decisions concerning the resource that is their major source of power. They compete for power within the oil arena and they reserve the right to use oil as a weapon in wider political games. Given the politics of oil, and the domestic instability of many

OPEC governments, how credible is an OPEC promise to increase production if a shortfall has political ramifications? And if an unintended interruption occurs, how likely is it that OPEC will be able to restrain the high-absorber members from charging what the market will bear? If, as is probable, they cannot, consumers will have paid higher-than-market prices in normal times in return for broken promises.

Would the benefits exceed the costs? Basically, consumers would gain a formal framework for debating production (and price) decisions that are now entirely in OPEC hands. Bilateral diplomacy can have some of the same effect. How much is it worth paying for this framework?

These questions do not mean that conversations with producer states are not useful, or that restoration of an international oil regime is not a worthy long-term goal. Various bilateral and multilateral discussions are essential. But efforts to reconstruct a satisfactory regime are unlikely to be fruitful unless hard questions have been carefully thought through. The volume at hand provides raw material for such thinking, but poses few of those questions and gives disappointingly few of the answers. □

## The state of Arab science

Ziauddin Sardar

*Science and Science Policy in the Arab World.* By A. B. Zahlan. Pp.205. (Croom Helm: 1980.) £13.95.

THE past decade has seen scientific and technological activity in the Middle East really come alive. While much of this activity is little more than simple transfer of equipment, expertise and personnel, there are, nevertheless, a number of projects which aim to make a real contribution to science development in the area and provide it with an indigenous base; to this end a number of technological universities and specialized institutes have been established to meet some of the more demanding needs of manpower and research.

The scale of this transfer of technology and its associated problems are in many respects unique and unparalleled, and demand urgent and detailed scholarly attention. Thus one turns to Antoine Zahlan's book with the hope of seeing these developments charted, analysed and placed in an appropriate scientific, social and political context. Indeed, few would be better qualified for such a job.

With so much to relate and analyse, it is sad to report that Zahlan has missed an excellent opportunity. His book is not just weak in content and rather limp in its

analysis; worse, it is a book apparently based almost entirely on publicity brochures and official handouts. Probably the best part is the introduction where Zahlan allows himself some critical consideration. However, from that point onwards, the book consists of straightforward description, potted history and dubious statistics.

The opening chapter presents a general view of the growth of scientific activity in the Arab World. Zahlan uses three basic sources for his information: UNESCO's *List of Scientific Papers Published in the Middle East (1948-1955)*, the now defunct *Arab Science Abstracts (1973-1975)* and *Who is Publishing in Science*. I would not be able to say anything about Arab science on the basis of these sources. Further I do not believe, as Zahlan does, that "scientific productivity measured in terms of publications of academic institutions is highly correlated with their scientific standing as assessed by leading scientists; it is also related to other outputs such as inventions, patents and the technological performance of the economy". These sorts of criteria for scientific productivity may be applicable to highly developed economies with sophisticated scientific infrastructures, but not to developing economies where scientists have more pressing concerns than

INTERNATIONAL JOURNAL OF

# coal geology

**NOW  
PUBLISHED**

**Editor-in-Chief:**  
**W. SPACKMAN,**  
Pennsylvania State  
University, PA, U.S.A.

**COAL GEOLOGY** is a new international journal committed to treating the basic and applied aspects of the geology and petrology of coal in a scholarly manner. Its scope encompasses -

- the genesis of coal and coal seams, including studies of modern coal-forming processes and environments

- the metamorphosis of coal materials in coal seams and dispersed in other rock types
- the geology of coal measures including stratigraphic, structural, geomorphic, paleogeographic, paleoecologic, hydrogeologic, palynologic, paleozoologic and paleobotanic facets of the subject
- the petrology and petrography of coal and coal seams including coal mineralogy, geochemistry and the chemical and physical constitution of coal.

The journal aims to stimulate the development of the science of coal geology in all parts of the world and to facilitate the dissemination of information on coals from all continents to all those who can benefit from such information.

**Types of contributions to be published are:** papers describing original research results; proceedings of symposia; surveys, reviews, book reviews, overviews, of recent literature, and letters to the editor.

publication. Zahlan himself is aware of the shortcomings of his methodology. However, no one is really any wiser at the end of the exercise.

As Egypt has the most highly developed scientific infrastructure in the Middle East, Zahlan appropriately devotes a whole chapter to the country. It is very much a historical discussion that traces science development in Egypt from 1951. An attempt is made to chart the development of scientific activity by measuring the increases in BSc and PhD degree holders (what is an Egyptian PhD worth, in real scientific terms, anyway?). Most of the statistics are taken from government ministries and technical institutes and no attempt is made to indicate the level of reliability of the figures. After Egypt, scientific activities in "selected countries" are presented: five pages on Kuwait, just over two on Iraq, less than a page on Saudi Arabia — which has one of the most rapidly expanding scientific bases in the Middle East, with astronomical sums being spent on science and technological development — and a half-page on Syria. Is that all that is happening in these countries and in the Middle East as a whole? Is nothing going on in Sudan, Algeria, Tunisia and Jordan?

After a similarly patchy and brief treatment of scientific manpower, we reach the last three chapters on funding, international and regional cooperation, and science policy, where at least an attempt has been made to be more thorough. The chapter on funding does manage to bring out both the channels being developed to fund scientific research and development and the resources available to capital-rich and capital-poor Arab states. The chapter on international and regional cooperation amounts to little more than the minutes of meetings of the Conference of Ministers of Arab States Responsible for the Application of Science and Technology to Development, and relies heavily on national papers submitted by Arab states to the recently held UN Conference on Science and Technology for Development. It is certainly not scholarship, neither is it good journalism, but it works as an account of recent history. This is also true of the chapter on science policy; here the commentary suffers by uncritical reproduction of material from brochures and annual reports such as that of Cairo's National Research Centre.

So, what value can one place on *Science and Science Policy in the Arab World*? The book has little of value to say about science policy, and even less about science, in the Middle East. But the book works, to a certain extent, as a history of science in the Middle East in general, and Egypt in particular, during the 1950s and 1960s. It is surprising that Zahlan has nothing much to say about recent — post-1975 — developments in science and technology. He seems to have overlooked the controversies about "Arabization" of

science, planning and developing technical institutions and universities, scientific bureaucracies and the debate on Islamic science. Perhaps these omissions are deliberate, but some discussion of these issues would have saved him from the accusation that the book is remarkably boring. Perhaps Zahlan feels that he has

said it all elsewhere in one of his many excellent publications. If this is so, then why write such an empty book? □

*Ziauddin Sardar is Middle East Science Consultant to New Scientist and author of Science, Technology and Development in the Muslim World.*

## Landau in retrospect

H.B.G. Casimir

*Landau: A Great Physicist and Teacher.* By Anna Livanova. Pp.217. (Pergamon: 1980.) £10, \$22.50.

Landau in 1936

LEV Davidovich Landau (1908–1968) was a brilliant theoretical physicist, an outstanding teacher and a striking personality, with an influence spreading far beyond the circle of his students and co-workers; his merciless criticism may have antagonized some of its victims, but he was most helpful and encouraging to anyone he considered worth helping. These characteristics are clearly brought out in Anna Livanova's well-written book. Although it is neither an exhaustive biography nor a critical appraisal of the whole of Landau's contributions to physics, the author has succeeded admirably in re-creating the image of this great man and in explaining to a general reader his ways of working and teaching.

The book opens with a brief biography. Landau was born at Baku and entered the university there at the age of 14. In 1924 he moved to Leningrad, graduating in 1927. Livanova gives a short but lively description of his student days. He learnt a little from his professors, quite a bit from discussions with fellow students — but most just by himself.

In 1929 he set out on an extended visit to western Europe and England. He went to see Pauli at Zürich, collaborated there with Peierls and wrote his famous paper on

diamagnetism (the description of which, by Livanova, leaves something to be desired). At Cambridge he met Kapitza, the beginning of a lifelong friendship, but of even greater influence on Landau were his contacts with Niels Bohr at Copenhagen. Livanova reports that Landau later regarded Bohr as his one and only teacher. That may seem surprising; I cannot think of two prominent physicists who differed more widely in their approach to teaching. Livanova calls attention to this difference, but in my opinion she does not sufficiently stress this point. I believe Bohr's influence was so important because his way of looking at physics was complementary to Landau's self-taught virtuosity. Landau had far more in common with Pauli in that they possessed comparable intellectual power and mathematical skills, and both could on occasion be redoubtable critics. Even so, there was a profound difference in their choice of subjects.

In 1932 Landau became head of the theoretical division of the Ukrainian Physicotechnical Institute at Kharkov. There he began teaching in earnest, collaborated with the experimentalists — especially with Shubnikow who had set up a cryogenic laboratory — and published a number of important papers. He left Kharkov in 1937 for Moscow and there he remained as head of the theoretical division of Kapitza's Institute of Physical Problems until his death in 1968; he always refused to become head of an institute of his own.

After a serious motor car accident in 1962, Landau became practically an invalid. One can sympathize with Anna Livanova in not entering into details concerning these later years, but I find it regrettable that, although she hints at difficulties at Kharkov, she does not mention that Shubnikow was arrested and never heard of again, and that Landau spent about one year in prison in 1938 and 1939 and might have perished but for Kapitza's courageous intervention.

For me, the most fascinating chapter is that concerned with "The School of Landau". This shows Landau at the height of his powers and gives a lively picture of his particular style and methods.

About half of the book is devoted to a description of Kapitza's work on the superfluidity of liquid helium and Landau's theoretical work in this field. The author preferred to consider one important and characteristic contribution of Landau's in detail instead of discussing superficially the whole of his work, and in

this she has been most successful in epitomizing the essence of Landau as a scientist. I have only one objection. No mention is made of the analogous and simultaneous experimental work of Allen and Misener at Cambridge, or of the theoretical work of F. London and of Tisza, who predicted second-sound several years ahead of Landau. The work of Landau was hardly influenced by these parallel developments, but the reader should know of them and that Landau's work, important though it was, was neither the only nor the final step towards a theory of superfluidity.

The final chapter, "Dau Away From Physics", recounts some amusing anecdotes but is hardly profound analysis. When I knew Landau at Copenhagen in 1930 and 1931 he was in a state of transition from shyness and reticence to the sociable and self-assured man of later years. He was then already classifying all things. Physicists, people in general and girls in

particular, books, poems, motion pictures, they all received marks from one to five (one the very best, five the worst and three just acceptable). Such grading also entered into his discussion of human relations. A couple where the man was a five, whereas the wife ranked a full three was unsatisfactory and should be broken up. In retrospect such considerations seem to me the immature and not even very witty self-defence of a sensitive and vulnerable man. Livanova takes them more seriously. In those faraway days Landau was not a happy man. Livanova mentions his claim that by his rational approach to human problems he succeeded in teaching himself to be happy. Did he really? I wonder. □

*H.B.G. Casimir studied theoretical physics at Leiden, Copenhagen and Zürich, worked in low temperature physics at Leiden and later joined the Philips Company at Eindhoven. He was for several years President of the European Physical Society.*

## Emilio Segrè on physics and on physicists

John Stachel

*From X-Rays to Quarks: Modern Physicists and Their Discoveries.* By Emilio Segrè. Pp.337. (W.H. Freeman: 1980.) Hardback \$20, £11.80; paperback \$9.95, £5.40.

EMILIO Segrè is one of that group of extraordinarily gifted physicists that gathered around Enrico Fermi in the late 1920s, a

group whose members contributed so much to the development of nuclear and elementary particle physics in the ensuing decades. Like Fermi, Segrè came to the United States in 1938 and worked on the A-bomb project during the Second World War. After the War he returned to Berkeley, where he worked primarily in high-energy physics. An experimentalist,

he shared the 1959 Nobel Prize in physics with Owen Chamberlain for the discovery of the anti-proton.

This book is based on lectures in which, as he says, "I tried to show not only the main discoveries but also the way they were reached, the personalities of the leading physicists and the errors committed before the right path was found". A prospective reader should not be misled by the title: the book is about the development of atomic, nuclear and elementary particle physics and "... does not pretend to be a history of modern physics. It is, rather, an impressionistic view of the events as they appeared to me during my scientific career ...".

Segrè gives fascinating accounts, from his perspective, of the discovery of the electron, X-rays, radioactivity; the old and new quantum theories and special relativity; nuclear structure and nuclear energy; particle accelerators and high-energy physics. The discussion is quite ample until about 1960. More recent developments, and accounts of related areas of physics, are treated in much less detail. For example, quantum electrodynamics, lasers and masers, the Mössbauer effect, superconductivity, astrophysics and biology are crowded into one chapter of 20 pages. In a final chapter, "Conclusions", Segrè points out trends toward greater specialization, industrialization, abstraction, and growing ties with technology in the current development of physics.

While an attempt is made to make the achievements of the major physicists "understandable to the layman", "Some knowledge of physics ... is necessary". Most formulae, however, are relegated to ten appendices ranging from "Stefan's law; Wien's law", to "Quantum Mechanics in a Nutshell".

Most semi-popular survey books of this type seem to be written either by theoretical physicists or non-physicists, and tend to overemphasize theoretical achievements and/or adopt an overawed attitude towards modern experimental techniques. It is therefore valuable to have a book written by such an eminent experimentalist. While he does not neglect the theoretical developments or the theorists, there is a better sense of balance, and of the interplay between experimental achievement and theoretical advance, than in similar books I have read. Since it is an avowedly personal account, Segrè does not hesitate to give his evaluations of the styles of work and personalities of the physicists he is discussing, or to illuminate the text with personal anecdotes and reminiscences. The book is also enlivened by numerous well-chosen illustrations, which really add a great deal of impact to the text. A reader comparing photographs of laboratories and sketches of experimental set-ups in the first few and in the last few chapters, for example, cannot avoid being struck by the growing industrial-

Eight Nobel prize winners at the 1960 Rochester meeting. From left: E. Segrè, C.N. Yang, O. Chamberlain, T.D. Lee, E. McMillan, C.D. Anderson, I.I. Rabi and W. Heisenberg.

ization of experimental research in particle physics, also apparent from the text:

With a pun of dubious taste, I could say that it is no longer sufficient to be a Rutherford, but one must be a Rutherford-Ford, meaning that the physicist must have at least some of the qualities of an industrialist and of a businessman [p.294].

Clearly, Segrè identifies "the physicist" here with the elite of the scientific community. He does not note that if some scientists are to be industrialists and businessmen, this implies that many other scientists and technicians must be workers and wage labourers. To carry his pun a step further, today there is a Reuther-Ford division among scientists (Walter Reuther was the head of the US Auto Workers trades' union).

The comments of a leading physicist such as Segrè on men and events, his views on the development of physics and its place in the scheme of things have an intrinsic interest. But the question naturally arises: how reliable is such an unashamedly personal account? I have the impression that, overall, it is a rather reliable source of information, but have only checked the chapter on Einstein with any care. Judgements of personality will naturally tend to differ. Against Segrè's view of Einstein:

He was not averse to playing the role of the great scientist; clearly, he enjoyed it. Perhaps this explains some of his affectations, his strange manner of dress, and some habits that may have been for show. After all, he was an admirer and friend of Charlie Chaplin [p.97].

one might want to set that of Leo Szilard, who was more closely associated with Einstein:

He is a man as free from vanity as I have ever seen. I have heard him talk to an audience of a thousand in German where he was at his best, and he talked to them as he would talk to a few friends gathered at his fireside . . . If you meet him you are struck with his great modesty and his great simplicity of heart [*Leo Szilard: His Version of the Facts* (MIT Press, 1978) p.12].

As to biographical information, the chapter is fairly accurate, but I must report that there are several errors. For example, Einstein's academic career between 1908 and 1912 is incorrectly given on p.88, which also speaks of Einstein as disturbed by "the anti-Semitic atmosphere" in Prague at that time. The account of Einstein's theories is generally quite good, although Segrè gives more of an operationalist twist to Einstein's development of special relativity than I think is justified. More serious is the statement on p.95 that the experimental effects predicted by general relativity "are small and difficult to observe, so that even now there is no absolute and unequivocal

confirmation of the general theory of relativity". While certainly true, it seems to imply that Segrè believes that some other theories have been absolutely and unequivocally confirmed. This and other statements (for example the first paragraph of p.292) make it clear that philosophical problems of physics are not Segrè's strong point.

No account of the development of nuclear physics can avoid some discussion of the development of nuclear weapons, and the impact of this development on the modern world as well as on the physics community itself. Segrè gives such an account, and makes a number of interesting comments on the personalities and roles of J. Robert Oppenheimer and Ernest O. Lawrence, for example. His stance is that of an enlightened member of the US scientific establishment; one cannot find any searching criticism of either the scientific or political establishments here. His account would have to be supplemented from other sources by anyone seeking a thorough understanding of the origins of our present nuclear predicament. I do not mean to imply by this that Segrè is not well aware of the problem. In the few pages he devotes to "the influence of science on the human condition", as he puts it, he states his views:

. . . science enhances human power. It also permits (at least approximately) anticipation of the consequences of certain courses of action. However, the process of decision at both the individual and the state level is dictated not by science but rather by obscure factors that I understand only dimly. They seem to me to be largely irrational, possibly dictated by behavioural forces, evolutionary drives, or subconscious demons. We thus see courses of action that to an outside observer appear totally irrational and destructive in their consequences. The armament race is an outstanding example. Because science enhances human power, it makes these foolish pursuits more and more dangerous, so much so that they may imperil the survival of the species . . .

While the scientist has the specialized knowledge of his discipline, on other subjects he is pretty much prey to the same dark forces as is anybody else. His training and education may help him to overcome some of his irrational urges, but the idea that the objective, cool scientist is above the crowd is fallacious. This should be recognized by the scientists and by the public at large. Scientists are not priests of a magic religion [pp.288-289].

## Nuclear technology for the layman

Malcolm C. Scott

*Unlocking the Atom: A Hundred Years of Nuclear Energy.* By Malcolm Longstaff. Pp. 175. (Frederick Muller: London, 1980.) £7.95.

THE story of the development of nuclear energy is striking, both for the intellectual excitement which it has generated as well as for the intense political and moral arguments which have surrounded its use for weapons and for peaceful purposes. Yet, paradoxically, there have been few books which have attempted to cover these developments, particularly the technical aspects, in a way which makes them accessible to the general reader.

Despite the disclaimer in the preface — "... all I have been able to give is a sketchy account of some aspects, and particularly those which interest me most" — the scope of the book is broad. It starts with the discovery of uranium, radioactivity and fission and discusses the work leading to the two atomic bombs dropped on Japan. The post-War development of nuclear reactors for plutonium production is then covered, leading on to the start of the non-weapons orientated reactor programme. The main features of the principal power reactors in use around the world are

outlined, followed by chapters on uranium and its fabrication into fuel (including the use of lasers for enrichment), fuel use and reprocessing, and radioactive waste disposal. There are then separate chapters on safety, on energy and the place of nuclear power, and on other uses of nuclear energy. Finally, in "Looking Ahead", the author touches on some of the current arguments relating to nuclear power (for example, the question of the blackmail value of plutonium and the possible role of thorium in separating the peaceful and non-peaceful uses) and outlines the principles of nuclear fusion. Throughout the book there are well-chosen photographs and numerous other figures.

The author keeps to his intention to give "little chemistry and no mathematics", yet, nevertheless, manages to provide a comprehensive technical coverage of the subject. In doing so he defines the terms which he uses in a non-technical way, so that the lay reader should not find it necessary to read with a technical dictionary at his elbow.

There are a few inconsistencies — for example, the abundance of uranium-235 is given variously as 1 part in 140, 1 part in 139 and 0.3% (1 part in 333: this is certainly a

typographical error). Nevertheless, they are few, and the general tone of the text is one of technical correctness and authority. Yet, despite these undoubted virtues, there is something lacking: it is simply that the author has not succeeded in making the field as enthralling as he found it during his 24 years with the United Kingdom Atomic Energy Authority. Instead, one is left with the uneasy feeling that the book reads like a succession of the carefully worded, technically correct, but bland handouts favoured by public relations officers, particularly in the nuclear industry. The sense of excitement aroused by the initial discovery of fission is missing, as is any sense of the enormous technological achievement in harnessing nuclear power.

After all, the reason why nuclear power bears the brunt of the anti-technologists' onslaught is precisely because it is seen as *the* high technology, an almost unique amalgam of science and engineering. Yet none of this emerges. Everything is under control, doubts are smoothly assuaged and technology rules supreme.

Nevertheless, for the reader who is prepared to accept these limitations, the book provides an accessible and comprehensive survey of the nuclear scene at a level which invites a wide readership. □

*Malcolm C. Scott is Senior Lecturer in the Department of Physics, University of Birmingham, in charge of the MSc course on the physics and technology of nuclear reactors.*

## Life as we know it: does anyone else?

Paul Davies

*Life Beyond Earth: The Intelligent Earthling's Guide to Life in the Universe.* By Gerald Feinberg and Robert Shapiro. Pp.480. (Morrow: 1980.) Hardback \$14.95; paperback \$7.95. *Earth and Cosmos.* By R. S. Kandel. Pp.270. (Pergamon: 1980.) Hardback \$30, £13.50; paperback \$14.90, £6.95.

*Life Beyond Earth*, proclaims the publisher's blurb, "is the result of a three-year collaboration between a theoretical physicist and a biochemist . . .". That sounds like a recipe for disaster, but the end product is remarkably coherent, if a little prolix. It is also somewhat pretentious, because it presents a range of ideas, varying from uncontentious standard biochemistry to the most outrageous and bizarre speculations, in a deceptively uniform and scholarly format.

It is, of course, the outrageous ideas that make this book such fun to read. The authors pin their colours firmly to the mast in Chapter 1: "We believe that most other attempts . . . have not been sufficiently imaginative in examining the possibilities for extraterrestrial life". To remedy this state of affairs, the reader is invited to consider the astonishing prospect of living creatures inhabiting the most unlikely of habitats — wallowing in the molten interior of the Earth, bobbing about inside the Sun, crawling over the surfaces of neutron stars, or floating serenely and nebulously in interstellar space. This is all good sci-fi stuff, but my main misgiving is that while the mere existence of a source of free energy and a mechanism for self-organization are certainly necessary conditions for the appearance of some form of life, can we really believe, as the authors assume, that they are sufficient?

A related problem to the happy prospect of a Universe teeming with exotic life forms is that it is far easier to believe in the evolution of intelligence, once life

has actually gained a foothold, than in the initial appearance of living things. Yet if intelligence abounds in the cosmos, we would expect it to be conspicuous. Where is the alien technology, some of it presumably billions of years more advanced than ours? Unfortunately, Feinberg and Shapiro almost completely ignore the subjects of intelligence and alien communities, so do not attempt to face this central issue.

It would be misleading, however, to over-emphasize the bizarre in this book. The authors provide a valuable service in, for example, drawing attention to the distorted public image of the Viking experiments on Mars, popularly believed to have excluded the possibility of life there. In fact, as the authors' careful analysis shows, the results were ambiguous, and the experiments in any case left a lot to be desired in their underlying assumptions about Martian biology.

One can also be persuaded by their argument that the search for extraterrestrial life contributes hugely to the motivation for the general exploration of space. Public disappointment that space probes have not yet positively encountered even the tiniest form of life has contributed to the widespread disillusionment with these expensive enterprises. Yet the most likely abode for life in the Solar System — Jupiter — has still to be closely explored.

Inevitably, for a book that tackles a subject for which no known subject matter yet exists, *Life Beyond Earth* contains liberal doses of philosophy. Specially singled out for attack are those whom the authors dub as "carbaquists" — biochemical faint-hearts who believe that life based on the chemistry of carbon and water is the only possibility. As a physicist, the carbaquist viewpoint has always seemed to me chauvinistic; biochemists are doubtless more conservative.

Another delicate issue concerns the need for a clear definition of life. Superficial criteria such as the ability to reproduce, response to environment and so on are also displayed by systems that are normally regarded as inanimate, so Feinberg and Shapiro adopt a sort of global definition wherein life is manifested through the activity of a biosphere; that is, one should look to the highly organized and complex structure of interlocking organisms as an unambiguous indicator of life.

At the end of the day we are still left with the depressing fact that the discovery of extraterrestrial biospheres is unlikely to occur in the twentieth century, so all books of this sort really amount to little more than speculation, or at best educated guesses. Nevertheless, there is a real need for us to examine fresh perspectives of mankind and his place in the Universe. With that in mind, I found the book entertaining and generally informative.

In contrast to this ambitious work, *Earth and Cosmos* by Robert Kandel is more modest in aim though wider in scope. The author also provides a cosmic perspective of mankind by discussing in detail a whole range of physical processes that are relevant to the structure of the Earth and its immediate environment. This book is full of fascinating information, ranging from continental drift to the pollution of the atmosphere. There is an extensive discussion of both meteorology and climatology, and a detailed review of the Earth's motion. *Earth and Cosmos* makes good reading for non-specialists who want to know more about the planet we live on. □

*Paul Davies is Professor of Theoretical Physics at the University of Newcastle upon Tyne.*

## Cosmic questions

Joseph Silk

*The State of the Universe.* Edited by G.T. Bath. Pp. 199. (Oxford University Press: 1980.) £8.95, \$24.95.

DESPITE its obscure origin and intemperate past, the Universe has made a good recovery. Conditions have stabilized over the past several eons, and practically all observers now agree that a recession is with us for some time to come. However the long-term outlook remains controversial — some predict that the rate of inflation will eventually drop, heralding the onset of a long era of deflation; other forecasters, perhaps a majority, maintain that the inflation rate will hold steady into the remote future. A vocal minority even persist in finding evidence that the inflation rate is accelerating.

This situation must seem familiar to the student of economics. Likewise, cosmologists also have their differences. It

may seem strange to the layman that experts should disagree on whether the Universe will perpetually continue to cool down, to attain inexorably the ultimate energy crisis, or whether it is destined to overheat and implode into a brilliant fireball, hotter and more intense than anything imaginable by human beings. The uncertainty arises because the currently available indicators are often contradictory; the cosmologist has considerable scope for rejecting evidence that may not fit his model, especially if the evidence is incomplete and tentative. A choice still remains between the "Heat Death" of the Universe and the "Big Squeeze".

Yet our knowledge of the Universe is increasing at an unprecedented rate. The availability of observatories in space has enabled astronomers to study the Universe over much of the electromagnetic spectrum that is inaccessible from ground level, from gamma-rays to infrared radiation. And modern technology has revolutionized ground-based observing. The caricature of the earnest astronomer peering through a telescope in a cold, dark observatory dome is a myth that has long been displaced.

The modern astronomer punches in coordinates on a computer console and views the stars on a video display in a brightly lit room crammed with sophisticated electronic instrumentation. The aim is to probe ever deeper into the mysteries of the Universe, by furthering our understanding of the structures within it, from stars to galaxies, alone and in their great clusters.

Astronomers are now able — albeit barely so — to trace images of ordinary galaxies so distant that their light was emitted before the Earth was formed. In principle, with sufficient information about such systems, one could directly infer their distances and decide whether the rate of expansion of the Universe has changed significantly over this time-scale. The future of the Universe could then be predicted unambiguously. It seems likely that within the next one or two decades, provided that governments continue to make the necessary commitment to science, advances in technology, both ground-based and in space, will enable detailed studies to be made of remote galaxies at the observable edge of the Universe.

*The State of the Universe*, based on the Wolfson College Lectures given at Oxford in the Spring of 1979, provides a fascinating and highly readable account of several of the major developments that have taken place in astronomy and cosmology over the past decade. Eight leading scientists who have played key roles in many of the discoveries cover a diverse array of topics, ranging from G.E. Hunt on the exploration of the planets to D.W. Sciama on the origin of the Universe. Especially memorable is the contribution by R. Penrose on black holes, for its lucid account of space-time singularities. M.J.

Rees writes on galaxies, their nuclei and their origin, and R.J. Tayler describes current views on the origin of the chemical elements. Hunt's beautifully illustrated chapter is one of the highlights of the book, providing a full and timely account of the newly acquired knowledge of the planets from Mercury to Jupiter. Remaining chapters include D.E. Blackwell on the stars as suns, K.A. Pounds on the X-ray Universe and F.G. Smith on new ways of seeing the Universe. Geoffrey Bath is to be commended on having co-ordinated an extraordinary lucid array of timely contributions from a group of the most eminent, and certainly among the busiest, of British astrophysicists.

On reading *The State of the Universe* one cannot fail to be impressed by the immense

vistas that the explosive progress in astronomy has revealed. Much is poorly understood: indeed, a radically new approach to physics may be required if we are to discover the origin of the Universe, for example. But enough has fallen into place for us to be confident that our theories enable us to understand how much of the Universe entered into its present state. Prediction of its future evolution now becomes feasible. We can already do this for stars: it may not be long before enough data is at hand to determine definitively the future of the Universe, no less. □

Joseph Silk is Professor of Astronomy at the University of California, Berkeley, and author of *The Big Bang*, published earlier this year by W.H. Freeman.

## Tuning in to astronomy

David W. Hughes

*Stargazers*. By Colin Wilson. Pp.271. (Hodder and Stoughton/Doubleday: 1980.) £10.95, \$15.95.

COLIN Wilson, the Colin Wilson who wrote *The Outsider*, *Introduction to the New Existentialism*, *Strange Powers* and a host of other titles, has now turned his attention to astronomy. He has written a fascinating account of how he thinks astronomers tick today, did tick in the past and should tick in the future, if, that is, they ever wish to solve the "fundamental question". What is the question? Bertrand Russell once said that the aim of philosophy is to understand the Universe. Wilson urges us to go a step further. The question is not just "what is the Universe?". It is "what is the *purpose* of the Universe?". Purpose, a word that makes all good scientists shudder. How should we — dry, dusty, intellectual

astronomers, tied to our telescopes, computers and respectable thought processes — delve into the understanding of the purpose of things? Wilson reveals his answer by frequent use of such phrases as "flashes of second sight", "supra-logical processes", "paranormal" and "intuitive insight". We are not told to abandon our scientific principles, we are simply encouraged to recognize that they are incomplete. There is always more than meets the eye.

The book divides into three sections. The first is a review of ancient cosmologies. Why should our ancestors build Stonehenge, what was the real purpose of the pyramids, did the ancient Egyptians know about the precession of the equinoxes? Wilson refers often to bicameralism and has obviously been much affected by Julian Jaynes's book *The Origin of Consciousness in the Breakdown of the*

Lord Rosse's giant six-foot reflector at Birr Castle in Ireland

**Bicameral Mind.** The brain is apparently split into a left half which is the home of rationalist, logical and scientific thought and a right half which houses artistic feelings and intuitive insights. Human development has led to a changeover in the dominant section. Civilization has suppressed the messages from the right brain and allowed the left brain to take over.

The second section of the book deals with the life histories and scientific achievement of some of the great renaissance scientists, Copernicus, Brahe, Kepler, Galileo, Newton and Herschel. The ghosts of Koestler's *The Sleepwalkers* and Dreyer's *A History of Astronomy from Thales to Kepler* haunt these pages.

The third section brings us firmly to the present day and traces the acceleration of

astronomical discovery that has occurred since Einstein's gravitational theory and the advent of quantum mechanics. Planetary exploration, radio astronomy, big bang cosmology, black holes, the origin of life — all are touched upon. Throughout the text echoes the Wilson message that there is more to our astronomical Universe than science can understand. The investigators must try and tune into this ethereal suprahuman influence on our destiny in a manner similar to that used by our ancient ancestors.

I enjoyed reading this book. It was fun. The style is excellent, the production standard and the illustrations are superb. But I continually had an uneasy feeling. It is an axiom that you should not believe all that you read; the reader of this book should not, and Colin Wilson should not

either. He has a regrettable tendency to regard the printed word in the same light as the tablets of Moses. Many eminent authors are quoted — Hoyle, Koestler, Motz, Taylor. When discussing Hoyle's *Lifeclock* and *Ten Faces of the Universe*, Wilson states that "No-one is going to quarrel with what they say". What? Scientists always question what other people say. The scientists such as Galileo, Kepler and Newton who are discussed in Wilson's book thrived on it. So should the readers of *Starseekers*.

But still, I congratulate Colin Wilson. Once you pick the book up it is hard to put it down. Interesting thoughts and problems sparkle from every other page. □

David W. Hughes is a Lecturer in Astronomy and Physics at the University of Sheffield.

## James Six and his thermometer

W. D. Hackmann

*The Construction and Use of a Thermometer.* By James Six. Introduction by Jill Austin and Anita McConnell. Pp.123. (Nimbus: London, 1980.) £15.

THIS small book reproduces the papers of an almost totally forgotten eighteenth century man of science, James Six (1731 – 1793), the descendant of a refugee Walloon family of silk weavers who settled in Canterbury during the reign of Elizabeth I. He was one of a score of amateur scientists who, through their individual small contributions, made scientific progress possible during the eighteenth century.

His tastes were typical of the contemporary intelligensia; painting, astronomy, electrical experiments with the new-fangled frictional electric machines, and meteorological observations. He invented a maximum and minimum self-registering thermometer in 1780; a worthwhile contribution for which he was awarded a Royal Society Fellowship in 1792. His thermometer, in which the extremes of temperature were recorded by sliding indexes, has survived as a popular domestic instrument. With it he observed the night-time inversion of temperature, a phenomenon not explained by meteorologists until the following century.

The largest portion of the book is taken up with a reproduction of Six's *Construction and Use of a Thermometer*, published in 1794, and essentially a summary of his three papers on thermometry published in the *Philosophical Transactions* with the addition of a chapter on the deep-sea use of his instrument. Eight pages are devoted to his other scientific communications. The bulk of these are his seven letters to the *Gentleman's Magazine*, a popular organ

for the amateur scientist. In 1770 he described a comet later known as Lexell's Comet. Its orbit was calculated by the American astronomer David Rittenhouse and Six's observations largely agreed with this. In 1771 and 1781 he recorded the appearance of two other comets. Other topics dealt with were the 1784 heat wave, William Herschel's recently discovered "Georgian Star" (Uranus) and a severe frosty spell in 1789. Also reproduced is a letter from the archives of the Cambridge University Library, written in 1785 by Six to a student friend of his son on the use of his thermometer. This series is terminated by a charming obituary of Six, also from the *Gentleman's Magazine*.

The only Six-type thermometer known before the researches of Austin and McConnell was the one in the Museum of the History of Science at Oxford. However, it is not contemporary, having probably been made in the 1820s for Charles Daubeny whose chemistry laboratory was housed in the present basement of this Museum. The authors have identified 26 thermometers made by Six and now part of the King George III Collection at the Science Museum in London, and another specimen of obscure origin at the Copernicus Museum in Rome. These are described in some detail and the subsequent development of the instrument is also given.

All in all, this small, attractively-bound volume not only adds a little to the history of thermometry, it also gives us another glimpse into the world of eighteenth-century men of science. □

W. D. Hackmann is Assistant Curator of the Museum of the History of Science, University of Oxford.

An original maximum and minimum thermometer by James Six, c.1782.

Science Museum, London

# Mathematics for the non-mathematician

P. T. Saunders

*Handbook of Applicable Mathematics.* Chief editor Walter Ledermann. Vol. I *Algebra*. Edited by Walter Ledermann and Steven Vajda. Pp. 532. (Wiley: 1980.) Subscription price for core volumes £27.50, \$75 each, single volumes £32.50, \$85.

UNLIKE their colleagues in physics, workers in the biological and social sciences have generally received very little training in mathematics. Few of them know more than a bit of calculus and some elementary statistics. As a result, they can find themselves totally unable to understand the increasing number of papers in their fields which employ more sophisticated mathematical techniques. Nor is it easy for even the most determined of them to do anything about this. It can be exceedingly difficult for a non-mathematician just to discover where to look up something, and even then he may be not very much further ahead. Mathematics is a cumulative subject; every new idea tends to depend on many that have come before. So he is likely to find that the explanation of the concept he is interested in is in terms of several other concepts which are equally unfamiliar. And as if that were not enough, at least some of these may originate in a different branch of the subject and not even be defined in the book he has consulted.

The *Handbook of Applicable Mathematics* represents an attempt to help "users of mathematics who are not professional mathematicians" when they find themselves in this awkward position. On completion it will consist of 16 volumes. The first six, called "core" volumes — *Algebra, Probability, Numerical Methods, Analysis, Geometry and Combinatorics, and Statistics* — are intended to cover all the mathematics the non-specialist is likely to encounter. There will also be ten "guide books", showing how mathematics is applied to different fields such as chemistry, economics, sociology, management, medicine and so on.

According to the editors, the aim of the *Handbook* is that "professional adults" needing to understand a particular mathematical idea will be able to find in it "just what they want to know". They have therefore tried to make the articles self-contained, to allow the reader to turn directly to the topic in question, rather than start at the beginning of the book. There is an elaborate cross-referencing system throughout the entire *Handbook*, so that any unfamiliar term or result can be located quickly and without searching through other works. They also claim to have "gone to great lengths to ensure that no branch of mathematics is omitted which is useful, and conversely that none is included which is not".

In some respects, the impression given by *Algebra*, the first of the core volumes

and the only one so far available, is encouraging. The general standard of writing and exposition is good, and the authors have kept in mind the desirability of explaining to the reader in plain language what is going on and what some of the definitions "really" mean.

Viewed in the light of the claims made in the introduction, however, some important shortcomings appear. While the explanations are clear and often illustrated by examples, the pace often seems too fast for a newcomer to the topic, and there are no exercises. There are inconsistencies between the chapters with regard to the amount of detail included; this is always a problem in multi-author texts but more could have been done to combat it, especially in such an ambitious work. Further, the selection of topics does not appear to have been made with the care and ruthlessness promised in the introduction; perhaps an analyst might agree that the long account of decimal expansions (without, incidentally, any real mention of other bases) is necessary, but two pages on quaternions seems an avoidable luxury.

The real problem with this book, however, is that in trying to cater for all levels of mathematical competence in one work the editors have set themselves an impossible task. There is a limit to the speed with which mathematics can be assimilated. Most of us can learn a new mathematical idea if it is clearly explained to us in language we can understand. And we may even manage to learn a second new idea based on the first. But before we can grasp a third new idea, and a fourth, we generally need some time and practice to enable us to become familiar with what we have just been taught. Many of the less essential topics which are included in mathematics courses are there for just that purpose. If we try to go on before we have allowed the first ideas to sink in, we are unlikely to understand the later ones, because they will be being explained in terms of ideas which are not yet a secure part of our mathematical vocabulary. So an explanation which is suitable for someone who has a good background in mathematics cannot be made suitable for someone who has not just by referring the novice back through a chain of earlier explanations.

So far as can be judged from the first volume and a proof copy of *Probability*, and without seeing any of the guide books, the *Handbook of Applicable Mathematics* will be of most value to those who already know rather more than the average amount of mathematics. They will find it a useful aid, but if it had been designed specifically for them it would have been a lot better. As it is, it tends to fall between two stools, with too much detail for reference and not enough for real learning, and despite its

virtues many potential users may not feel it worth the considerable outlay. As for someone with only a minimal previous knowledge, he is unlikely to find that the series will open the rich storehouse of mathematics to him, even with the effort the editors warn him will sometimes be required. He would do better to try to acquire a solid foundation from some of the good — and much cheaper — elementary textbooks which are already available. There is, as has been said before, no royal road to geometry. □

P. T. Saunders is a Lecturer in Mathematics at Queen Elizabeth College, University of London.

## Whither geography?

K. J. Gregory

*Geography: Yesterday and Tomorrow.* Edited by E. H. Brown. Pp. 302. (Oxford University Press: 1980.) £10, \$29.95.

THE 150th anniversary of the Royal Geographical Society provides the *raison d'être* for this volume. Founded in 1830, the RGS was third in the world following the establishment of geographical societies in Paris in 1821 and Berlin in 1828; like them its function included the encouragement of exploration and discovery, a tradition which has persisted to the present day.

Although the first professor of geography in Britain was appointed in 1833 at University College, London, the subject took firm root in Oxford and Cambridge, and between 1883 and 1924 the RGS gave grants to these two universities to foster its development. The Geographical Association, concerned with geographical education in schools, was founded in 1893, and in 1933 a group of geographers formed the Institute of British Geographers to provide an outlet for research publications because it was felt that the *Geographical Journal* had insufficient space for both research papers and accounts of exploration and travel.

Today, for the first time, both the President and the two Honorary Secretaries of the RGS are university geographers. Such strong links with university geography have not always featured during the course of the 150 years which are charted by T. W. Freeman in the first third of the book. Freeman concludes that the struggle for recognition of the subject has now been won; the way in which this was done and the subject recognized and established in education is explained in the following contribution by N. J. Graves.

To reveal the yesterday and tomorrow of geography as an academic discipline, the subject is divided into 12 subdisciplines,

each discussed by a different author. Inevitably, perhaps, they do not adopt a consistent approach. Some contributions are stimulating reviews which concentrate on major developments and prospects; W. R. Mead on the essence of the regional ideal, A. G. Wilson on the position of theory in human geography and Emrys Jones on the scope of social geography consider three aspects of the subject that have been prominent and partly sequential in geographical thinking during the past two decades. Other authors give a chronological summary of development in a particular branch of geography — geomorphology, land use survey, leisure and recreation, and medical geography — with passing reference to the role of the RGS. A third type of contribution provides a state-of-the-art summary of the approaches adopted by contemporary research schools; this is very effective in discussions on climate and on biogeography, tends to be somewhat compressed for historical geography, and embraces trends beyond the subject for surveying and mapping and in the chapter "Water as a Geographical Issue". Not all geographers will agree that this range completely portrays the current academic spectrum. In particular, one might have expected a consideration of philosophical approaches to the subject, and of urban geography which has been responsible for a very substantial proportion of the research output in human geography since 1960.

The overall impression of geography given by the book is that it is a subject not as disintegrated as the titles of the chapters might indicate. It is evident that more energy has been devoted to some branches, such as geomorphology, than to others, climatology for example. It is artificial to erect a barrier around a subdiscipline, and it is shown how the development of theory and of surveying and mapping, and of branches such as historical geography and medical geography, have flourished by contact with and exposure to proximal disciplines.

The debate as to whether the physical could, and should, separate from the human part of the subject appears in at least one incisive discussion, but it is apparent from a number of branches that contributions to practical problems associated with earth hazards, and social, recreation and leisure, and medical geography arise because the subject spans the interface between human activity and environment. The geographer thus has to be conversant with some techniques from the pure and applied sciences and others from the humanities and social sciences. This is at once part of the characteristic skill of the geographer. Also clearly emerging as a recurrent theme is the importance of spatial analysis — perhaps geography is really about maps, although the map may today be in the form of an equation, a satellite image or a data bank.

In the final thought-provoking chapter,

W. R. Mead, a former Honorary Secretary of the RGS, epitomizes geography as a synthetic subject in which the regionalists are closer to the heart of the subject than most. Whereas the regional ideal used to be the only crumb of integration that was offered, we now have further applicable links offered by the study of water, biogeography, land use, leisure and recreation, and medical geography. Perhaps geography tomorrow will find its integrity not solely dependent upon the classic regional approach and a book produced for the 200th anniversary could promulgate even closer liaison between the branches of the subject.

The editor introduces the volume as

## To boldly go. . .

Sarah Bunney

*To the Farthest Ends of the Earth: 150 Years of World Exploration.* (The History of the Royal Geographical Society 1830–1980.) By Ian Cameron. Pp.288. (Macdonald/E.P. Dutton: 1980.) £10.95, \$29.95.

I ASSUME it was primarily the shape rather than the subject matter that determined the prominent position of this vignette on a preliminary page of Ian Cameron's book in honour of the Royal Geographical Society, but it was an apt choice nonetheless. The engraving represents two important aspects of Victorian exploration — the appalling hardships endured by the explorers as they strove to satisfy their curiosity, and the disappointments and controversies that accompanied many nineteenth-century expeditions. In particular the picture draws attention to the sadly misguided preference of British Polar

being designed to do many things, among them to explain what is geography, what do geographers do and what use is geography. In answering these questions, particularly the second, the book is a great success. It is enjoyable to read and is extremely stimulating. Students and others should be encouraged to buy this book, but having read it they may find, like me, that an index would have been invaluable because the volume certainly deserves to become a standard work of reference. □

*K. J. Gregory is Professor of Geography and Chairman of Department at the University of Southampton.*

explorers for man-hauling their equipment instead of using dogs. It was this policy, which received the Society's support for some 50 years, that contributed to repeated disappointments on Arctic expeditions and eventually to Captain Scott's defeat in the race for the South Pole in the early 1900s.

Ian Cameron, who had access to the Society's records while writing his book, is scrupulously fair in his treatment of this unhappy story and of the other difficulties that beset many of the expeditions in the Society's first 75 years. Personalities, warts and all, are vividly brought to life. Mr Cameron also gives a balanced account of the Society's more recent — and somewhat insensitive — handling of the choice of leader for the Everest expedition. In the event this expedition was a glorious success and it is, of course, achievement and not failure that this book is mostly about. There is plenty of solid, but never heavy description of the most important expeditions of the past 150 years, accompanied by excerpts from notebooks, dispatches and contemporary accounts in the Society's *Journal*.

All this makes for such fascinating reading that I would have preferred more of the highly readable text and fewer illustrations — even though many of the latter are delightful, particularly the polished sketches by Baines and the early photographs. My one serious complaint concerns the maps. It is ironic that, in this of all books, these are heavily drawn, inadequate and, in at least one case (the Musandam map on p.224), inaccurate. Furthermore the two contemporary maps included are almost illegible, they lack captions and it was only on reading the acknowledgements that I learnt of their source and date.

This book cannot be a comprehensive history of the RGS, and Mr Cameron has wisely concentrated on the expeditions to areas that have long been the favourites of armchair travellers — the Arctic and Antarctic, the Himalayas and Africa. New to me were most of the early explorers of Australia and the brave Pundits who secretly and at great hazard to themselves surveyed on foot almost the whole of the Eastern Himalayas in the 1850s to 1870s. Childhood heroes — Burton, Speke, Livingstone, Stanley, Nansen, Shackleton, Scott, Hunt, Hillary and Tenzing (but only one heroine, Florence Baker) are included. Mr Cameron also gives credit to many other explorers, less well known but equally deserving of fame, who doggedly helped fill in the blanks on the maps. I am only sorry that room could not be found in this catalogue of illustrious names for some

After the summit of achievement: Hillary and Tenzing after the first ascent of Everest, May 1953.

mention of the Arabian travels of Wilfred Thesiger and Freya Stark.

Mr Cameron brings readers up to date with accounts of some of the recent, increasingly scientific, expeditions that the RGS has supported — to the Mato Grosso (1967–1969), the Musandam Peninsula (1971) and the Mulu rain forest in Sarawak

(1977–1978), for example. The book ends with a chapter on the role of the Society today as it continues to advance geographical knowledge. It is a quieter role, without the glamour and heroics of the past, but no less important for that. □

## Stonehenge and its times: a layman's and a scholar's view

R.J.C. Atkinson

*The Enigma of Stonehenge.* By John Fowles and Barry Brookoff. Pp.128. (Cape/Summit: 1980.) £6.95, \$19.95. *The Age of Stonehenge.* By Colin Burgess. Pp.402. (Dent/Biblio: 1980.) £12, \$25.

THESE are two very different books, which have in common only the name of Stonehenge in their titles. The first is the result of a most happy collaboration between an English novelist and an American photographer, both of genius, to give a unique picture of Stonehenge itself. The second is a sober and most scholarly interpretation (John Fowles would call it clinical) of the prehistory of the British Isles during the *flourish* of Stonehenge.

Fowles's short account begins with his own first happy visit to Stonehenge as a child, and with his last, less happy because the stones are now closed to the public. His summaries of the archaeological background and of the sequence of building can be faulted in detail by the pedantic specialist; but they are based on a wide and critical reading, and they are written with a delusive ease and with an informed humanity which puts to shame the earnest

but pedestrian locations of most other recent writers about Stonehenge, myself included.

He asks: "What is Stonehenge for?" For me this is an unanswerable question, because I do not think that the mute material evidence of prehistory can tell us, except in a quite trivial sense, what people thought in the remote past, but only, up to a point, what they did. This is not to say, as Fowles hints, "a pox on all speculation"; but speculation and valid inference are two very different things, and must be distinguished, perhaps better than Fowles does.

In his longest chapter, "The Moon-Mirror", he perhaps accepts too easily some of the astronomical uses ascribed to Stonehenge by Hawkins, Hoyle, Newham and Thom. Moreover, he confuses the Metonic Cycle with the period of rotation of the lunar nodes, and falsely explains the position of the Heel Stone, as a possible marker for the mid-point of the azimuthal limits of most northerly moonrise, in terms of the latitude of Stonehenge. He also infers, quite incorrectly, that the absence of any discussion of astronomical theories from my own book *Stonehenge* (Hamish

Hamilton, 1956) was intended as a "monumental snub" to Hawkins, Hoyle and Thom. Far from it. My book was written in 1955, before any of these theories were published, and has since been reprinted only with appendices to bring the results of later excavation up to date.

Fowles's luminous text ends with an historical and personal appreciation of Stonehenge-in-the-mind, and not least in the mind of that eerie and disturbing seer, William Blake. He protests throughout against "a quite unnecessary polarity in twentieth-century society between pure science and impure speculation". This echoes what I wrote in *Nature* (265, 11; 1977). The science is far from pure, because much of the basic data are at best uncertain, and at worst corrupt. The speculation is likewise not impure, merely because it is speculation; but it is not inference compelled by the evidence of Stonehenge-on-the-ground.

Barry Brookoff's photographs, unnumbered and uncaptioned, match John Fowles's text in their sensitivity and imagination. No one has better frozen in print an image of Stonehenge. His

From *The Enigma of Stonehenge*

occasional use of a wide-angle lens gives a sense of spaciousness which the monument itself belies, though one which echoes some of William Stukeley's engravings of 1740. Occasionally a Sun or Moon has been added by photomontage for dramatic emphasis at far more than natural size. Not the least haunting of these photographs capture, as none has before, the texture of the surface of some of the sarsen stones, in which each beholder will see his own private vision.

This book, in words and images, will enlarge the consciousness of every visitor to Stonehenge, past and future.

Colin Burgess's book will likewise extend the thinking of every British prehistorian, and of colleagues abroad. It is a major advance in the synthesis of the new evidence which has become available, almost explosively, from excavations and the analysis of museum collections during the past 20 years for the period of 3,000 years from 3,200 BC, which corresponds roughly to the use of Stonehenge.

He divides this into five periods, each identified by a type-site, and each characterized in his view by specific practices or trends, in ritual architecture for worship or burial, and in the design and manufacture of artefacts. This is a convenient chronological device for avoiding the constraints of ill-fitting radiocarbon dates with their present state of uncertainty. He gives also, however, a list of 215 radiocarbon dates in their raw (uncorrected) form. One may ask whether these, when corrected, may not provide a better framework than a series of largely arbitrary periods which, because they are new, may be adopted and maintained long after they have ceased to be significant. He rejects, rightly, the old and now outmoded divisions of the conventional Neolithic and Bronze Age.

Burgess's main thesis is that tribal territories had already been fixed by the end of the fourth millennium BC, and that thereafter cultural change took place by the adoption of innovations across persisting tribal boundaries, with local adaptations increasing in proportion to the distance from the primary source. This is a possible model, though the one which rests on a number of quite unverifiable assumptions, and one which rejects explicitly the "invasion hypothesis" that has long been dominant in explanations of British prehistory.

In his proper desire to emphasize cultural continuity, however, he has

perhaps underestimated the impact of the Beaker people coming from across the North Sea and the Channel in the middle of the third millennium BC. Whether this was an invasion, an incursion or an immigration, or a series of any of these processes, on whatever scale, is largely a semantic question. What is evident is that there was a fairly rapid innovation in material culture, superimposed on native practices which survived by absorption. This cannot be explained except by an incoming from abroad, and a break in the continuity of native traditions. Burgess does admit, quite rightly, that at the end of the "Age of Stonehenge" there may have been an influx of foreigners who established the succeeding "Age of Hill

Forts", though they are far less well represented in the archaeological record than the Beaker people.

This is a book for specialists in British prehistory, and not least for university students. It is well illustrated by photographs of sites and objects. The numerous line-drawings of plans and artefacts have been rather over-inked and thus harshly reproduced, and the inclusion of north-points and scales is a little capricious. Minor defects apart, it is a major contribution to the understanding of a formative period of our prehistoric past. □

## The rediscovery of ancient Ebla

J.M. Munn-Rankin

*EBLA: An Empire Rediscovered.* By Paolo Matthiae. Translated by C. Holme. Pp.237. (Hodder and Stoughton/Doubleday: 1980.) £12.95, \$14.95.

THE excavation in 1974 and 1975, at the north Syrian site of Tell Mardikh, ancient Ebla, of a mid-third millennium palace with some 20,000 cuneiform tablets written in a previously unknown Semitic language was an event of outstanding importance for historians of early urban society in the Near East.

Prior to this discovery, archaeological and textual evidence for developments in Syria during the Early Bronze Age (c. 2900–2000 BC) was meagre. As compared with the earliest centres of civilization, Sumer and Egypt, relatively few Syrian excavations had penetrated below second millennium levels and of these most were stratigraphic sondages. At only a few major sites, mainly in the north-east, had more extensive excavation produced significant evidence of urban settlement. Literacy was attested only at Mari on the Euphrates where a Semitic language was written in the cuneiform script of Sumer. Of the population it could be said only that it was probably of mixed ethnic origin and that its social structure ranged from primitive nomadism to complex urbanism. It was, however, apparent that the urban civilization of Sumer, in existence by the second half of the fourth millennium, had

played a major role in the formation and subsequent development of Syrian civilization, the main impetus for the expansion of its influence being the need for the timber, stone and metal in which southern Iraq is deficient. As regards the political geography of Syria, a limited amount of information was provided by the records of Sumer, among the earliest being the campaign reports of Sargon and Naram-Sin of Agade (c. 24th and 23rd centuries BC) which list cities conquered on expeditions to the Mediterranean. Among them is Ebla.

This inadequate picture of the early culture and history of Syria is now being transformed by the excavations of Paolo Matthiae of Rome University at Tell Mardikh. In this report on their progress, he describes and assesses the significance of the finds made between 1964 and 1976. The site was occupied from the latter half of the fourth millennium until the sixteenth century BC, but work has so far been concentrated on the cities of the mid-third and early second millennia. Excavation of the latter has made a major contribution to knowledge of the architecture and art of that period, but of far greater importance are the unique discoveries in the earlier level.

Here was a major urban centre with central acropolis and lower town, perhaps covering some 56 ha, encircled by a defensive wall. Excavation has exposed part of an acropolis palace, including an

administrative block with archive rooms and magazines. The destruction of the building by fire preserved much of its contents: carved furniture, miniature sculpture, seals, decorative stone inlay, pottery and one of the largest collections of cuneiform tablets ever found. The great majority of these tablets are administrative and economic in content but there are also literary compositions, lexical texts, royal edicts and correspondence and treaties. Because of their number and the difficulties posed by the Eblaite language, it will be many years before their publication — entrusted to an international committee — is complete, but preliminary studies provide a foretaste of the rich harvest of information which will eventually be available on the population, economy, institutions, religion, literature and political history of the city.

Any reconstruction of the society and history of Ebla must at this stage be provisional. Matthiae's account, based on the textual evidence available when the 1977 Italian edition went to press, has to a certain extent been amplified and clarified by subsequent research, mainly in the field of linguistics. The population was predominantly but not exclusively Semitic and the closest connections of the Eblaite language are now considered to be with Akkadian, the speech of the Semitic element in the population of Sumer. A considerable amount of information is available on state and municipal administration but there remain many fundamental questions, answers to some of which may not be provided by the type of text found so far. For instance, was kingship hereditary or elective? What proportion of the population was in the service of the state, the temple or large land-owners and under what conditions?

Whether Ebla was the leading state of northern Syria and the centre of an extensive empire, as maintained by Matthiae, requires further investigation, but its conquests included Mari and it was in diplomatic contact with states as far east as the Tigris valley, notably Ashur with which it concluded a commercial treaty. Its far-reaching trading operations are documented by an archive dealing with the state-controlled export of woollen cloth. The destinations of the consignments are distributed over an area extending from Palestine to central Anatolia and from the Mediterranean to Ashur and Kish in northern Sumer. These names of towns and kingdoms provide much new information on political geography but although some are well known, such as Megiddo and Lachish, the majority cannot be located and there are numerous uncertain readings.

The civilization of Early Bronze Age Ebla was formed by the fusion of Syrian and Sumerian cultural traditions. The former are at present most evident in language, religion and architecture; the latter in the use of the cuneiform script, in

literature, art and certain administrative practices. The extent to which political and social institutions were influenced by those of Sumer is not yet clear. Until the lower levels of the site are investigated, the environmental and cultural factors which contributed to the rise of urban life at Ebla must remain a matter of speculation. However, archaic Sumerian elements in the political concepts and art of the palace period suggest that Sumer provided the initial stimulus, probably in the late fourth millennium when it had trading colonies in Syria.

It seems probable that the palace and its archive, which spans the reigns of five kings, was destroyed either by Sargon, founder of the Agade dynasty of Sumer, or by his grandson, Naram-Sin. According to one school of thought, the form of the script employed at Ebla requires the earlier dating. Matthiae prefers the later on the basis of certain artistic features.

The rediscovery of Ebla is of outstanding importance for the early history of civilization in the Near East. The texts and archaeological finds recovered from the palace have revealed the presence in northern Syria in the mid-third millennium of an established urban and literate Semitic society, as advanced as that of contemporary Sumer. The nature of the impact of Sumerian civilization on what was clearly a strong native cultural tradition can already be defined in considerable detail. The texts, when published, will illuminate the history not only of Ebla but also of the numerous states with which it had political and commercial contacts. The significance of the information obtained from Ebla cannot as yet be fully assessed but Matthiae indicates the areas in which it is to be sought. □

The art of Ebla: wooden figure of a king from Palace G.

## The appeal of archaeology

Gail Kennedy

*The Cambridge Encyclopedia of Archaeology.* Edited by Andrew Sherratt. Pp.495. (Cambridge University Press: 1980.) £18.50, \$35.

THE goal of this handsomely produced volume is to "summarize the present state of knowledge over the whole field of archaeological inquiry". While *The Cambridge Encyclopedia of Archaeology* does not quite achieve that somewhat quixotic goal, it does succeed to an impressive degree.

The overall value of the volume, however, rests as much with its clear presentation of the new directions taken by archaeologists since the 1960s, as with its summarization. In the past most books of this large-format genre have reflected

the earlier emphasis of archaeologists on the exquisitely formed artefact or imaginatively recreated structure; such books have relied more on lavish illustrations and less on informative text. While this volume is indeed well illustrated, the emphasis is on maps and schematic diagrams rather than artefacts, which here are pictured simply and in black and white. The maps — of physical geography, migration patterns, political domains and urban or village street plans — are among the most beautiful and informative in print.

While the maps and diagrams will undoubtedly set a publishing standard for the future, the text is no less attractive and informative. It clearly reflects the trend among archaeologists away from the antiquarian-collector attitudes of the past and

towards data synthesis, broad regional analyses and model building. It demonstrates clearly that archaeology today is problem-orientated rather than artefact-orientated. The problems now under examination by archaeologists often centre on the dynamics of interactions between man, his technology and the environment. Systems theory and feedback models provide valuable ways of examining such interactions, and indeed many of the sections in the *Encyclopedia* are structured either implicitly or explicitly around these conceptual frameworks.

A systems approach becomes a particularly useful tool in archaeology when analysing the emergence of entirely new levels of organization. No longer are such new levels viewed by archaeologists as periods of abrupt revolutionary technological or behavioural change, but instead are seen as periods of adjustment and readjustment to changing configurations of resources and knowledge. The origins of agriculture form one of the more intriguing applications of systems theory. At the end of the last glacial, environmental changes apparently provided both the opportunity and the necessity for the increasingly specialized exploitation of food resources. What is well demonstrated in the chapters on the origins of agriculture in the Near East Africa and the Far East is that this new and unique strategy for human survival occurred, apparently independently, in several areas. Thus, in each of these major regions, and in at least one centre in the New World, human populations responded to the changing post-glacial world in a recurring pattern of increased utilization of a small number of wild foods. It was this emerging dependency on wild foods which led to their ultimate control and domestication. And it was this control over local food resources that paved the way for an increasingly sedentary way of life.

The variety of subjects covered by the book is indeed encyclopaedic. While most of the chapters consist of regional analyses of important phases in human history — the origin and development of agriculture, cities and empires, for example — other relevant topics such as early human evolution and dating techniques have not been neglected. The geographical scope, however, is somewhat uneven. Of a total of 64 chapters, only seven (eight if one includes Oceania) are devoted to the archaeological history of the New World. While it may be conceded that the Old World was long the central focus of human development, surely the entire Western Hemisphere merits more discussion than these few rather perfunctory chapters. Moreover, certain major problems in New World prehistory, such as the probable timing and route of human entry, have not even been mentioned.

In the final analysis, the faults of *The Cambridge Encyclopedia of Archaeology* are few. The short, well-illustrated

chapters are suited for both browsing and more directed reading, while their content will inform all but the specialist. Although price is a drawback, this would be an extremely useful text for broad survey courses in archaeology. The consistent emphasis on method, theory and recent

research, the bibliography and broad geographical and temporal scope all combine to make this a volume with wide appeal. □

Gail Kennedy is at the Department of Anthropology, University of California, Los Angeles.

## Cancer: how much of a business?

D.G. Harnden

*The Cancer Syndrome*. By Ralph W. Moss. Pp.347. (Grove Press: 1980.) \$12.95, US only.

IT is usually assumed that those involved in cancer research are motivated by a desire to rid the world of the disease. While this may be partly true, intellectual curiosity and concern for individual patients are often the most potent driving forces. Ralph Moss, however, tells us something different. Cancer research in the USA is, he says, largely manipulated by big business in the hope of financial gain; manipulated by those who believe that a cancer cure will make a fortune for the holder of the patent and by those who fear that preventive measures will involve cleaning up a profitably polluted environment. The medical profession too, he suggests, are part of this conspiracy, favouring treatments which ensure a handsome profit.

It would be easy to dismiss Moss's book as inaccurate in detail and outrageously biased, but to do so would be to fail to acknowledge that some of the criticisms that he makes seem well aimed and that the issues he raises are of considerable importance. Unfortunately, he does not spell out or consider in any constructive way the main issue that he raises, namely "What is the proper relationship between the fundamental discoveries of biological science and the industry that can make these discoveries available to the general public?"

There are two central allegations around which the book is built. First, that orthodox treatment is unsuccessful and that the cancer establishment in the USA will take any steps to ensure that new developments which are not patentable are stifled at birth or as soon thereafter as possible. Second, that little emphasis has been placed on prevention because it would be more profitable to find a patentable cure and because prevention might involve fundamental and expensive alterations in industrial practices.

Is there any truth in either of them? For the commonest cancers it is true that the results of conventional treatment are not good. In breast cancer the five-year survival rate is approximately 50% (and, as Moss reminds us, five-year survival is not cure), while for lung it is a disastrous 5%. Even worse, neither figure is improving. When we say that improvements have

occurred over the past few years it is essentially in cancers that are uncommon, such as Hodgkin's disease and in the childhood neoplasms such as Wilm's tumour. But many cancer patients are cured and many more are given a greatly improved quality of life, so there is, at least, some over-statement. However, when Moss points to over-optimistic propaganda about cures it is hard to disagree with him — we have a long way to go. He therefore suggests that we turn to unorthodox methods such as laetrile, Coley's toxin, hydrazine sulphate and vitamin C, and says that information that such methods are already successful has been deliberately suppressed. In a vitriolic attack on the Memorial Sloane Kettering Cancer Centre, the American Cancer Society and the National Institutes of Health, he accuses these institutions and specific individuals of blocking grant awards for research in these areas and of granting awards to others for their help in this process.

As a science writer sacked from the Memorial Sloane Kettering for misrepresenting the work of the Institution, Moss can hardly be without bias — but he is well informed. He shows that the governing bodies of the Memorial Sloane Kettering Cancer Centre and the American Cancer Society have a large representation of those whose business connections could lead to a conflict of interest. Obviously there are altruistic reasons why industrialists and financiers would wish to serve on the board of a cancer centre, but there could be less worthy reasons. Although overt attempts to influence scientific policy would obviously be resisted by the scientific staff, the possibility of indirect influences, especially by those who donate very large sums of money to the institutions, must be a matter for concern. Moss also points to the form of contract between the Memorial Sloane Kettering Cancer Centre and the chemical companies which seems to grant all the advantages to the companies. This is not an easy matter, and the link between industry and the scientist often poses a dilemma. Anyone in cancer research who has a connection with industry is liable to be accused of having compromised his scientific integrity. However, Moss is more concerned with undermining the present structure than with suggesting improvements and the important questions are left unasked.

It really does seem hard to believe that successful unorthodox treatments are suppressed because they are not patentable. If they were good then they would have been adopted in countries other than the USA where the allegations of corruption levelled by Moss do not apply. Moreover, Moss mentions, but gives scant attention to the need to protect the public from unscrupulous frauds. There are too many documented cases to ignore the fact that National Institutes of Health, the American Cancer Society and similar bodies have a duty not only to promote research, but also to protect the public from quacks. So the first charge is not entirely proven; nonetheless, Moss's book leaves an uncomfortable feeling that all is not well.

When he turns to cancer prevention (or the lack of it) he is on firmer ground. There is plenty of evidence that in the past, and also at present, some parts of industry have callously ignored the welfare of their workers. Moss revels in the horrors of asbestos and mesothelioma. These facts have been well documented elsewhere, however, and are no longer the main issue. He is quite wrong in saying that research into preventive methods has been ignored;

this only reveals his limited horizons. There is at present a great deal of activity in basic research laboratories and in industrial laboratories to find ways of preventing the widespread use of hazardous chemicals. Again, this needs collaboration between industry and basic research, but the relationship is not always an easy one. Any scientist who helps a company to sort out a problem is likely to be branded a consultant — and therefore suspect — by people such as Moss. This should not be so — the expertise in the universities and research institutes *should* be available to industry. On the other hand, it does cause concern that one distinguished scientist and government adviser should also be found to be a consultant for six large corporations and two manufacturers' associations.

The book is well written and easy to read. In an era in which monoclonal antibodies and the production of specific polypeptides by genetic manipulation are likely to become big business, it raises issues that have to be faced. The manner in which the issues are raised, however, leaves a rather nasty taste in the mouth. □

*D. G. Harnden is Professor of Cancer Studies at the University of Birmingham, UK.*

atherosclerosis may be a paediatric problem is dealt with. Although this is a prudent approach it is emphasized that proof is at present lacking. A brief chapter is devoted to inborn errors — principles and not details. The final chapter discusses the management of chronic diarrhoea in children.

The second volume, concerned with nutrition and growth, draws attention to the diffuse nature of the subject, the value of having different perspectives, and the fact that there are few "absolute" answers to the various problems such as standards for growth and dietary allowances.

The first chapter considers the problem of nutrient needs. In the absence of proper experiment, the tendency is to consider present intake as "ideal requirements". In the next chapter the complex interrelationships between genetic constitution and nutrition are discussed. The influence of non-dietary factors is dealt with, as also is the problem of metabolic anomalies.

Part II is concerned with the ages of man and is introduced by a chapter on maternofoetal nutrition which presents results of the 1969 longitudinal INCAP study. This leads logically to a consideration of the nutrition of the full-term and premature baby. The need for further work on the problems of the latter is emphasized. Four chapters are then devoted to the young child and discuss the normal and failure-to-thrive child, protein-energy malnutrition and obesity respectively. The adolescent, rapidly changing organism and the adult, stabilized situation between development and senescence are then discussed. Part III contains nine contributions which deal with aspects of growth monitoring and nutritional assessment and surveillance, and contains much practical information on different methods and useful tables of reference data.

Volume 3A starts with a discussion of nutrient requirements — what they are and the bases of recommendation — leading on to contributions concerned with energy requirements, the suppliers of energy and their interrelationships, the problem of energy exchange and the partition of food energy. The remaining four chapters deal with nutrients with special functions — proteins and amino acids, essential fatty acids, cholesterol and dietary fibre.

Volume 3B is introduced with a chapter on vitamins, mainly those of the B-group, as co-enzymes. There are five chapters on individual vitamins and one on iron-haemoglobin. The chapter entitled "Trace Elements" starts with a somewhat scant treatment of calcium, phosphorus and magnesium. There are useful discussions of drug-nutrient interrelationships and the effects of oral contraceptives on nutrient requirements. The final chapter on nutrition of the elderly has very much a North American bias.

Volume 4 is concerned with the metabolic and clinical application of nutrition.

## State of the art in nutrition

J.W.T. Dickerson

*Human Nutrition—A Comprehensive Treatise.* General editors R. B. Alfin-Slater and D. Kritchevsky. (Plenum: 1979/1980). Vol. 1. *Nutrition: Pre- and Postnatal Development* (edited by M. Winick), pp.495; £24.89, \$39.50. Vol. 2. *Nutrition and Growth* (edited by D.B. Jelliffe and E.F.P. Jelliffe), pp.450; £23.63, \$37.50. Vol. 3A. *Nutrition and the Adult: Macronutrients*, pp.290; £15.75, \$25. Vol. 3B. *Nutrition and the Adult: Micronutrients*, pp.424; £24.89, \$39.50. (Both edited by R.B. Alfin-Slater and D. Kritchevsky.) Vol. 4. *Nutrition: Metabolic and Clinical Applications* (edited by R.E. Hodges), pp.478; £23.63, \$37.50.

THIS large work has grown out of an idea "to provide the research investigator and the advanced graduate student with an up-to-date report on the state of the art". Originally intended as one volume, the treatise now has four volumes and one (Vol.3) has two parts.

Volume 1 deals with the role of nutrition in pre- and postnatal development, and starts with a discussion of nutrition and the metabolic development of mammals. Metabolic status at various stages of development is closely related to the quality and quantity of the nutrients consumed. The author (Hahn) suggests that the old idea that nutrients act directly on most cells must be discarded and

replaced by a concept that, mostly, nutrients have immediate and long-term effects by acting on selected endocrine cells, which then release their hormone to act on target cells. It is this combined effect which controls the development of enzyme systems, cells and tissues.

The development of the brain is important in controlling the ability of the organism to respond to its environment and malnutrition may, because of the time-scale over which the brain develops, have permanent deleterious effects upon it. The importance of this subject is reflected in several of the following chapters.

Nutrition and pregnancy is largely discussed from the viewpoint of the effects of disturbances in maternal nutrition on the growth and development of the foetus. The effects of nutrient excesses and of interactions of drugs with nutrients are briefly mentioned. This leads logically to a discussion of breast feeding by Jelliffe and Jelliffe who make the point that the matters that need emphasis are the same the world over.

The contribution on the interactions of nutrition and infection includes a discussion of the problem of the septic patient. In the chapter on the relationship of nutrition to dental development and disease the need is emphasized for more studies to explore the mechanisms and consequences of nutrient deficiencies to oral health. The recognition that

The first three chapters discuss the relationship of nutrition to disorders of the haematopoietic, nervous and musculoskeletal systems respectively. These chapters are not exhaustive and are not concerned with therapeutic aspects. The effects of essential nutrients on the gastrointestinal tract and the effects of diseases of the tract on the absorption and utilization of nutrients are dealt with, as also are the nutritional abnormalities occurring in liver disease. Here again there is no discussion of the possible role of nutrition in treatment. This is in contrast to the presentation on cardiac failure which is much concerned with therapeutic aspects and contains a useful table of drug-nutrient interactions of importance in congestive heart failure.

Discussion of the relationship of diet and nutrition to cancer is mainly concerned with their possible involvement in the aetiology of oncological disease, with little mention of the effects of the disease on the nutrition of the patient.

The ageing-nutrition-health triad is discussed by Watkins who points out that education is the prime catalyst for inducing change. The chapter on the endocrine system is concerned with diabetes, vitamin D, and parathyroid and thyroid disorders. Discussion of megavitamins and food fads is largely taken up with doubts about Pauling's well-known views. It is, perhaps, unfortunate that in a text of this sort some consideration is not given to the possibility that larger amounts of vitamins than the currently recommended allowances may have beneficial effects which are difficult to measure and therefore often dismissed as anecdotal.

There is a useful and well-referenced chapter on the effects of ethanol. Nutritional aspects of infectious diseases

are discussed and it is pointed out that nutritional supportive therapy should be employed to prevent or minimize the depletion of body stores during an infection, and to replace lost nutrients as expeditiously as possible during convalescence. Obesity is the most common nutritional disease in Western society. Assessment, risks and treatment of this poorly understood condition are considered. As a consequence of our poor understanding successful treatment is often elusive, and the demand for treatment has led to a multiplication of fad diets, examples of which are given. The final chapter contains a discussion of the interrelationships of nutrition and the kidney. Effects on kidney function and nutritional disturbances in the nephrotic syndrome, hypertension and renal failure are dealt with, as also are the principles of nutritional therapy.

These volumes are a useful addition to the textbooks available on human nutrition. They are not exhaustive, either in respect of subjects covered or the depth to which each subject is discussed, but the material is well presented and well referenced throughout. Moreover, the books have been produced to a high standard and are a pleasure to read. In spite of their inevitably high price, teachers of nutrition at degree level may well consider it worthwhile acquiring one or more of them. They can be said to have achieved their aim and to present in reasonable compass the present state of the art in a dynamic subject. □

*J.W.T. Dickerson is Professor of Human Nutrition at the University of Surrey and Consultant Adviser on Clinical Nutrition to the South West Thames Regional Health Authority.*

subject, of course, to the disabilities consequent upon their pre-operative brain damage.

Here we also had a neurosurgical preparation in which, with appropriate techniques that were lacking in the 1940s, one could investigate the cognitive capacities of the left and right hemispheres isolated from each other except through their brain stem connections. The preparation enabled workers to confirm, extend and fine the deductions that had previously been drawn from the effects of lateralized injury, namely, that the left and right hemispheres (in the majority of the population) are indeed primarily implicated in the exercise of linguistic and visuo-spatial skills, respectively. But because in the commissurotomy patient the left hemisphere has little knowledge of what the right hemisphere is doing (and vice-versa), the enticement of talking about these people as if they had two minds within a single body (brain? person? soul?) proved irresistible (and not only to popularizers). The lure of thinking about the patients in this way is, of course, much more exciting than patiently trying to comprehend the what, how and why of functional localization.

But worse was to come. The disconnected right hemisphere, conspicuously deficient in syntax and verbal reasoning, can yet support dreams, emotions, and a high level of non-verbal memory and intelligence. All that remained was to deify the distinction between the cerebral hemispheres: the left brain became the seat of a cold, calculating, logical and talkative mind, whilst the right brain sustained a warm, intuitive, emotional and artistic mind. In an era in which attitudes towards science are often ambivalent, what could be more attractive than to have science and surgery discover the reality, nay the material substrate even, of intuition, creativity and pure feeling.

Modern times are truly an ideal medium in which to culture the hundreds of articles and books that have attempted to disseminate "the right brain revolution" that Blakeslee describes. Yet there is a sense in which any sociological analysis provides too easy a let-out. Blaming the *Zeitgeist* never takes us very far. The real vacuum that such books attempt to fill arises from the failure of neuroscientists themselves to provide any significant theoretical account of functional localization. The evidence — from anatomy and pathology, and from recordings of the electrical and chemical activity of the normal intact brain — now overwhelmingly supports the notion that distinct cerebral regions are differentially involved in the exercise of higher cognitive functions. How and why this is the case we do not know. It could, however, be an interesting problem for someone to work on. □

*John C. Marshall is in the Neuropsychology Unit, Department of Clinical Neurology, The Radcliffe Infirmary, Oxford.*

## Abdication of reason

John C. Marshall

*The Right Brain: A New Understanding of the Unconscious Mind and its Creative Powers.* By T. R. Blakeslee. Pp.275. (Papermac/Doubleday: 1980.) Hardback £10, \$10.95; paperback £2.95.

THIS is another "popular" book on how to unlock the emotional and creative power of the right cerebral hemisphere. The volume recounts some of the evidence, from both normal and brain-injured people, that has led physicians and clinical psychologists to believe that considerable specialization of function characterizes different areas of the human brain. Blakeslee concentrates on inter- rather than intra-hemispheric localization and leaps somewhat wildly from datum to conclusion. For any reviewer who wants to dip into his repertoire of sarcasm, the volume will provide more than adequate stimulus — why is there no woman Beethoven, the author asks, and answers that the cerebral

hemispheres of women are functionally less differentiated than those of men. It is tempting to regard Blakeslee's offering as beyond satire and plunge immediately into instant sociology. Why do such books exist? What need do they satisfy?

The "right brain revolution" that Blakeslee and so many others have attempted to explain to a lay audience had its genesis in 1962. Two Los Angeles neurosurgeons, Philip Vogel and Joseph Bogen, revived and refined a surgical procedure for the control of pharmacologically intractable epilepsy. The operation involved sectioning the corpus callosum and the anterior and hippocampal commissures — the main fibre tracts that interconnect the two cerebral hemispheres at the cortical level. There can be little doubt that both the original and subsequent series of commissurotomy operations have been a success; patients whose intellectual and social activity had been severely compromised by generalized convulsions have been able to return to an essentially normal life, although still

# Carbonic metamorphism, granulites and crustal growth

R. C. Newton & J. V. Smith

Department of the Geophysical Sciences, University of Chicago, Chicago, Illinois 60637

B. F. Windley

Department of Geology, University of Leicester, Leicester LE1 7RH, UK

*Stabilization of early crust against melting by high radioactivity and against resorption into the mantle by fast convective overturn requires that water and heat producers were flushed upwards within 50 Myr of accretion. Creation of a refractory base of granulite by metamorphism associated with CO<sub>2</sub> vapour explains CO<sub>2</sub>-rich fluid inclusions in ancient high-grade rocks, minor-element depletions and local phenomena of arrested development of charnockite in Precambrian terrains. The hot-spot and plate-tectonic models of Precambrian crustal evolution lead to different schemes for CO<sub>2</sub> delivery to continental roots. New tectonic concepts may be needed to explain carbonic metamorphism and other features of early crustal evolution.*

THE continental crust consists of a heterogeneous assemblage of rocks whose crystallization ages fall into clusters dating back<sup>1</sup> 3,800 Myr. If earlier crust existed, it was presumably destroyed by resorption into the mantle or by meteorite impacts, by analogy with the Moon<sup>2</sup>. Radiogenic heat production would have halved during the period<sup>3</sup> 4,500 to 3,000 Myr ago, but even by 3,000 Myr the latest estimate of total heat production of the Earth<sup>4</sup> implies an average volcanic activity for the Earth's surface similar to that of Iceland at present<sup>5</sup>. The important problem is thus how the continental crust became stabilized in the Archaean era against melting at its roots, and against resorption into a rapidly convecting mantle.

The well exposed Archaean terrain of south-west Greenland contains areas of tonalitic gneisses with two discrete ages (Amîtsoq, 3,650 to 3,700 Myr; Nûk, 2,800 to 3,000 Myr).<sup>6</sup> Other terrains support the concept of major episodes of crustal accretion from partial melting of mantle, and the similarity of initial isotope ratios to model values for mantle evolution implies little contamination by earlier crust<sup>7</sup>.

Ancient terrains are generally metamorphosed into the amphibolite and granulite grades. The mineral chemistry of the granulites demonstrates reaction over a pressure range<sup>8</sup> ~7–12 kbar (0.7–1.2 GPa), which corresponds to a depth range of ~25–40 km before uplift in response to erosion and tectonic forces<sup>9</sup>. Granulite rocks contain much less H<sub>2</sub>O than lower-grade rocks with similar major-element chemistry: anhydrous pyroxene minerals are prominent in granulites whereas the hydroxylated minerals mica, amphibole and epidote are the mafic equivalents in rocks of amphibolite facies. Charnockite, a pyroxene-bearing rock of granitic composition, is a conspicuous type of granulite which dominates some granulite terrains (for example, southern India). Some charnockites have igneous precursors<sup>10,11</sup>, but some have been attributed to metamorphism of layered sediments<sup>12</sup> and anatexis mobilization of graywackes<sup>13</sup>.

Many granulites have lower contents of large-ion lithophile elements (for example, U, K, Th, Rb) and heavy rare earths than younger crustal rocks with similar major-element chemistry<sup>14,15</sup>. Heat-flow and heat-balance<sup>16</sup> calculations demonstrate that the lower part of the continental crust is strongly depleted in radioactive elements with respect to upper crustal rocks, and show that widespread crustal melting by intrinsic heat produc-

tion would have taken place in the Archaean unless the radioactivity was strongly concentrated in the uppermost part of the crust by some transport mechanism within 50–100 Myr after an accretion episode<sup>3</sup>. Hence granulites are the obvious candidates for deep continental interiors, and granulitization, either by igneous or metamorphic processes, or both, deserves detailed study.

A unique feature of many granulites is CO<sub>2</sub>-rich fluid inclusions in minerals, in contrast to H<sub>2</sub>O-rich inclusions characteristic of lower-grade metamorphic rocks<sup>17,18</sup>. Hence carbonic volatiles may be important in granulite metamorphism and continental stabilization<sup>9,15,19,20</sup>. For carbonic metamorphism to be applicable to entire continental bases, a large, possibly subcrustal, source of CO<sub>2</sub> would be needed. Carbonate-bearing peridotite is stable in the mantle to higher temperature than mica-peridotite<sup>21</sup>, and is a possible source of CO<sub>2</sub>. Interrelations among granulites, crustal growth, carbonic metamorphism and mantle storage of CO<sub>2</sub> are now examined with reference to simple tectonic models currently being discussed for evolution of Precambrian crust.

## Origin of granulites

It has been suggested that granulite terrains in general are the residues of crust depleted in H<sub>2</sub>O and lithophile elements by partial melting (anatexis), with removal of the melt phase to shallow depths<sup>22</sup>. However, there is much evidence against this hypothesis. K-rich granites and higher-level amphibolites are not complementary in either major or minor elements to many granulites<sup>9,15</sup>. Indeed, some granulites, such as the Madras charnockites<sup>23</sup> with granitic chemistry and high Fe/Mg, would themselves qualify as the out-melted fraction. In some migmatite areas, both out-melted and residual fractions are in the granulite facies<sup>24</sup>. Tonalitic gneisses have similar Ba/Sr in both amphibolite and granulite grades; the latter could not be residues from closed-system melting of the former because of greater preference of Ba over Sr for a melt fraction<sup>15</sup>. It has been shown that outmelting did not occur extensively during the 2,700 Myr granulite metamorphism of the Scourian terrain of the Scottish Highlands, the key evidence being preservation of the 2,900 Myr Sm–Nd age<sup>25</sup>. Although granulites cannot in general be anatexis residues, some pyroxene gneisses might be

residual fractions of mantle or deep-crustal melts<sup>26,13</sup>. The pronounced depletion of heavy rare-earth elements of many pyroxene gneisses may require a two-stage formation: original accretion of a basaltic pile and remelting of the basalt to produce tonalite at depths great enough to stabilize garnet in the residue<sup>15</sup>.

Granulite terrains contain a wide variety of bulk compositions matching the metamorphosed igneous and sedimentary components of lower-grade terrains. In Karnataka, India, the metamorphic facies changes southerly from greenschist to granulite<sup>27</sup>. Marbles, basic rocks, pelites, migmatites, Fe-rich quartzites and dominant tonalitic gneisses occur over hundreds of kilometres, and granulite metamorphism, which has affected all of these lithologies, is not obviously associated with partial melting and complementary residues. A similar situation exists in south-west Greenland<sup>9</sup>.

Although many or most granulites have not undergone extensive partial melting, a mineralizing pore fluid is needed to explain the coarse K-feldspar in pegmatoidal charnockites from Enderby Land<sup>28</sup> and Pallavaram, Madras<sup>23</sup>. Kinetic calculations (see ref. 29) show that growth of large garnets at metamorphic temperatures requires a flux. A pervasive fluid would help to transport minor elements<sup>15</sup>. The discovery of dense, CO<sub>2</sub>-rich fluid inclusions in minerals of granulites<sup>18</sup>, and the intimate connection between charnockite and CO<sub>2</sub>-rich inclusions over broad terrains, points strongly to the role of CO<sub>2</sub> in the metamorphism. In the Bamble terrain, southern Norway, fluid inclusions change from aqueous in amphibolite facies to carbonic in granulite<sup>17</sup>. The Kleivan pluton, south-west Norway, grades from normal granite with aqueous inclusions to charnockite with carbonic inclusions<sup>30,31</sup> over 5 km. In the zone of regional transition from amphibolite to granulite in Karnataka, patches of charnockite are locally developed in amphibolitic gneiss<sup>27</sup>. Irregular diffuse stringers of dark-brown charnockite obliterate the pronounced migmatitic banding of gneisses over a scale of 1 cm to 1 m. Amphibole and biotite of amphibolite give way to pyroxenes in patches of charnockite with no textural evidence of melting<sup>20</sup>. Temperatures could not have risen significantly over 1 cm to produce dehydration. Influx of CO<sub>2</sub> along shears was invoked to explain the dehydration. Similar patchy distribution of charnockite occurs in south-west Greenland<sup>9</sup>, south-west Sweden<sup>13</sup> and western Australia<sup>32</sup>. The fluid in cordierite from Finnish granulites has CO<sub>2</sub> mole fractions<sup>33</sup> ranging from 0.35 to 0.85; cordierites from some rocks in the amphibolite facies have much higher H<sub>2</sub>O/CO<sub>2</sub> than cordierites from Norwegian granulites<sup>34</sup>; and cordierites from shallow pegmatites contain no CO<sub>2</sub> in contrast to abundance in cordierites from granulites<sup>35</sup>.

This evidence for abundant CO<sub>2</sub> complements evidence from experimental and theoretical phase-equilibrium studies that granulite-forming fluids must have low  $P_{H_2O}$ . Mineralogical geothermobarometry of granulites consistently yields temperatures of 700–900 °C and pressures<sup>23,36</sup> of 7–12 kbar. However, many rock types yield granitic liquids at 650–700 °C and  $P_{H_2O}$  of a few kbar (ref. 37). In particular, the definitive charnockitic assemblage K-feldspar + orthopyroxene transforms to biotite + quartz or partially melted assemblages at water pressures above 0.7 kbar, regardless of the temperature<sup>38</sup>. To avoid melting, the water fractions of metamorphic fluids must be low, such as the 0.1–0.3 estimated for the amphibolite-to-granulite transition in the Archaean terrain of south-west Greenland<sup>9</sup>.

It must be emphasized that experimental work and geothermobarometry indicate that simple metamorphic dehydration reactions are not sufficient to account for the dryness and minor element depletion of granulites. Some overwhelming pore fluid diluent is called for, and the fluid inclusion evidence implicates CO<sub>2</sub>.

### Amount and source of carbonic fluids

The upper limit of  $P_{H_2O} = 0.3P_{total}$  for granulites from south-west Greenland allows rough estimation of the amount of CO<sub>2</sub> required for conversion of amphibolite to granulite over a

20-km thick layer of crust. A continuous flushing action is needed because H<sub>2</sub>O from the breakdown of hydrous minerals would otherwise dilute the CO<sub>2</sub>. For a conservative estimate of 1 wt% of H<sub>2</sub>O in amphibolitic gneisses and an ideal gas law, about 8 wt% CO<sub>2</sub> is needed ( $44/18 \times 0.7/0.3 \times 1$  wt%), or roughly 0.3 rock volume at average temperature and pressure. This much CO<sub>2</sub> is ultimately necessary to convert an amphibolitic crustal layer to granulite, and the supply may possibly be maintained over the duration of a metamorphic episode, say tens of Myr. The actual amount of CO<sub>2</sub> in the rocks at any instant may be very small, in the form of grain-boundary films.

Thin marbles and calc-silicates occur in greenstone piles and as metamorphic relics in Archaean high-grade terrains<sup>39</sup>. Calc-silicate rocks, possibly representing former limestones, are conspicuous locally in some terrains but are usually subordinate to associated charnockites and other granulites<sup>9</sup>. Although the graphite contained in many Precambrian metasediments<sup>39</sup> might react with H<sub>2</sub>O to produce CO<sub>2</sub> at high temperature and pressure, the mole fraction of CO<sub>2</sub> produced by reaction in a closed system is below 0.7 for a large range of  $T$  and  $P$  (ref. 40). Osmotic escape of H<sub>2</sub>, or fluid immiscibility<sup>41</sup>, might cause CO<sub>2</sub> enrichment.

Some authors have dismissed crustal sources of CO<sub>2</sub> as inadequate to produce the kind and degree of metamorphism observed<sup>9,20</sup>. However, it is very difficult to estimate the original CO<sub>2</sub> content of a highly metamorphosed section. Extensive evaporite sequences rich in carbonate and organic carbon have been recognized recently in the Archaean of Brazil<sup>42</sup>, and stratigraphy of this sort may have been more abundant than generally recognized. We emphasize here mantle outgassing as a more feasible CO<sub>2</sub> source<sup>9,19,43,44</sup>, while recognizing the inherent difficulty of assaying possible crustal contributions.

The present-day mantle contains substantial CO<sub>2</sub> in spite of extensive partial melting. Hawaiian volcanoes emit CO<sub>2</sub>-rich gases<sup>45</sup>. Mid-ocean ridge basalts contain CO<sub>2</sub>-bearing vesicles<sup>46</sup> and xenoliths of mantle peridotites contain fluid inclusions of nearly pure CO<sub>2</sub> (ref. 47). A high CO<sub>2</sub> activity is important for generation of alkali basalts and carbonatites<sup>48–50</sup>. Depending on the  $P$ - $T$  regime, the CO<sub>2</sub>-bearing phase in equilibrium with olivine and pyroxene of the mantle is either a carbonate (dolomite or magnesite), a CO<sub>2</sub>-rich melt, or a free vapour<sup>21,51,52</sup>. To provide 0.3 rock volume of CO<sub>2</sub> for 20 km of crust, 0.04 rock volume would be required from an assumed 150 km of uppermost mantle; this corresponds to ~1–2 wt% of carbonate minerals or interstitial carbonate-rich melt.

Mantle carbon, as represented by diamond and carbonatites, has a smaller amount of <sup>13</sup>C ( $\delta^{13}C \cong -6\%$  relative to the commonly used standard) than limestone, which averages about +20%. Carbon from the CO<sub>2</sub>-rich fluid inclusions of Bamble granulites is near the mantle value, which was used as evidence of a 'primary' carbonic fluid from the upper mantle<sup>53</sup>. However, graphite of biogenic origin is also very light<sup>42</sup>, and it is not clear how much this may have influenced the granulite fluid inclusion carbon. Isotopically light carbon is a necessary, but not sufficient, criterion of a subcrustal source.

If the whole Earth went through a vapourization stage at the end of accretion<sup>54</sup>, it is not obvious how to explain the presence of CO<sub>2</sub> and other volatiles (for example, <sup>3</sup>He) in the Earth's mantle<sup>55</sup>. Late accretion of cool volatile-rich material on to an Earth that had been cooled by intense volcanic activity during accretion<sup>4</sup> is more plausible. If the primitive mantle was effectively degassed during an early period of high temperature, some form of subduction is needed to carbonate the mantle. Recent experimental data suggest that some pelagic limestone, perhaps inorganically precipitated, might escape dissociation and melting during subduction into the mantle<sup>56</sup>. Carbonate-bearing peridotite is stable to higher temperature and should tend to resist melting better than mica-bearing peridotite above 26 kbar (ref. 21), during convective overturn of the mantle. Although there is no compelling evidence for plate-tectonic subduction in the early Archaean, assimilation of carbonate-bearing sediments into the crust may have occurred during

destruction of crust<sup>4</sup> before 3,900 Myr BP. If the Earth's mantle contained elemental carbon at the end of accretion, oxidation to CO<sub>2</sub> might have occurred during transportation to the surface by convective overturning, or by disproportionation of ferrous iron into ferric iron and iron metal at high pressure<sup>57</sup>.

### Phase-equilibrium constraints on carbonic metamorphism

Some experimental phase-equilibria<sup>58</sup> would allow partial remelting of a basaltic lower crust to yield tonalitic liquid and a garnet-bearing residue. The latter would provide a sink to explain heavy rare-earth depletion in granulite (that is, anhydrous) conditions. A two-pyroxene granulite of basaltic composition begins to melt to garnet + clinopyroxene + liquid at ~1,190 °C for 11 kbar and 1,230 °C for 15 kbar (ref. 58). In the subsolidus region, olivine and orthopyroxene are progressively eliminated with increasing pressure, and garnet becomes stable at ~10 kbar. A late Archaean geotherm<sup>3</sup> would allow dry basalt to melt to a garnet-bearing residue and a tonalitic liquid at ~12.5 kbar and 1,200 °C. The experimental melting relations place an effective limit of ~40 km on the thickness of the Archaean crust with this geotherm, which passes near a *P-T* estimate for Madras granulites<sup>23</sup>. Formation of carbonate-bearing scapolite in basaltic to intermediate compositions places limits on the conditions in which CO<sub>2</sub> may stream through the lower crust. Although calcic CO<sub>2</sub>-scapolite is stable by itself to very high temperatures at elevated pressures, the retention of CO<sub>2</sub> by basalt is limited by the reaction:

The *P-T* location of this reaction is not yet known, but a moderately large geothermal gradient (see, for example, ref. 3) would probably pass through the free-CO<sub>2</sub> field (right-hand side of the above reaction) for about the lower half of the crust. Details depend on the Na/Ca ratio of the plagioclase and the CO<sub>2</sub>/SO<sub>4</sub> ratio of the scapolite, and much further experimentation is needed.

A basaltic liquid rising from the mantle would release CO<sub>2</sub> during ascent, either because of greatly decreased solubility below 20 kbar (ref. 48), or because of crystallization. At 10 kbar, basaltic magma saturated in CO<sub>2</sub> and H<sub>2</sub>O releases a vapour with CO<sub>2</sub> mole fraction<sup>59</sup> near 0.9, and such a vapour would be rich enough in CO<sub>2</sub> to purge overlying crust until it became too diluted in captured H<sub>2</sub>O.

Another possibility is transport of CO<sub>2</sub> during crustal accretion by the dissolved volatile complement of primary tonalitic liquids generated directly by mantle melting<sup>9</sup> leaving a garnet-bearing residue, perhaps in a subduction zone. Evaluation of this and related possibilities requires discussion of tectonic mechanisms of Archaean crustal accretion.

### Tectonics of carbonic metamorphism

Because many granulites should still be buried and because many must have been destroyed by retrograde metamorphism, there is considerable doubt about the rate of generation of granulites throughout geological time. The simplest tectonic model involves continuous outgassing of CO<sub>2</sub> from the mantle into the lower crust. By analogy with the evidence for generation of crust<sup>1</sup>, the supply of CO<sub>2</sub> would have been episodic. Subduction of carbonate sediments and their assimilation into peridotite might replenish the mantle reservoir, and convective overturning would take newly carbonated peridotite under a continent where CO<sub>2</sub> could be released to cause carbonic metamorphism. However, a comprehensive model should consider the problem of the great concentration of granulites in the age range 3,000–2,500 Myr and show the relationship of these granulites to other components of the Archaean crust.

There is no agreement on the tectonic relationships between low-grade greenstone belts and high-grade regions of the

Archaean era, and simple analogies based on modern plate-tectonic<sup>60,61</sup> and hot-spot<sup>62,63</sup> models may be misleading because of possible change of convective style and melting processes in the mantle as heat flow declined. Hot-spot models are inspired by extrusion of large volumes of basalt at Hawaii and Iceland where generation of proto-continental nuclei may be occurring. Plate-tectonic models draw support from (1) calc-alkaline nature of island-arc volcanic rocks and probable andesitic composition of mean continental crust<sup>64</sup>; and (2) analogies between ancient rocks in granulite-gneiss Archaean belts and deeply eroded Cordilleran batholithic belts<sup>65</sup>. A linear sequence of ridge, trench and subducted slab is probably incompatible with the high heat flow<sup>4</sup> and unstable continental nuclei of early Archaean times. Perhaps numerous plume-like cells with radial rather than lateral spreading<sup>4,63,66</sup> partly coalesced into short ridges as the Earth cooled. It seems certain that a tectonic model for development of granulites in high-grade regions will not prove fully satisfactory until the relationship to greenstone belts is explained. However, the tectonics of ancient carbonic metamorphism will be discussed with reference to the contrasting hot-spot and plate-tectonic models to focus attention on the problems of CO<sub>2</sub> delivery to the lower crust.

### Hot-spot model

Basaltic magma from a rising mantle plume or diapir may escape to form a massive intrusion<sup>63</sup> under existing continental crust (Fig. 1a). Water is retained by amphibole in crystallizing basalt, and CO<sub>2</sub> escapes to flush out water from overlying crustal rocks<sup>18</sup> to produce a granulite front. On cooling, an underplated basaltic pile turns into amphibole-bearing eclogite, garnet granulite, or garnet amphibolite. Underplated crust becomes distended, as perhaps in the present western US, and deep, block-faulted grabens are filled with basic lavas and detritus to become greenstone belts or cratonic supracrustal troughs. Note that the apparent trough-like nature of greenstone belts may actually be due to post-deposition tectonics<sup>67</sup>. As the mantle

**Fig. 1** Hot-spot model of crustal growth and granulite metamorphism. *a*, Basaltic liquid from a mantle diapir (not shown) underplates existing crust, and crystallizing amphibole retains H<sub>2</sub>O. Doming of the crust results in massive grabens filled with volcanic and sedimentary rocks which become metamorphosed into greenstone basins (GB). A granulite front develops from carbonic metamorphism caused by CO<sub>2</sub> released either directly from the mantle or from crystallizing basalt. *b*, Steepening of the geotherm causes remelting of deep-seated rocks to yield a garnet-rich residue and uprising magmas. Resulting tonalite plutons rise through the crust causing isoclinal folding of greenstone basins. Further CO<sub>2</sub> streaming causes rise of a granulite front.

plume continues to rise, geothermal gradients steepen. The basaltic continental roots undergo partial melting to yield magmas of intermediate composition. These rise diapirically as tonalitic plutons which engulf the greenstone belts<sup>68</sup> (Fig. 1b). Escape of tonalitic magma leaves behind a mafic to ultramafic residue. Basaltic magma continues to escape from the mantle bringing further H<sub>2</sub>O and CO<sub>2</sub>. The key to this model is escape of CO<sub>2</sub> as a vapour phase at a pressure near 20 kbar while a secondary amount of H<sub>2</sub>O is either trapped in hornblende in the deep crustal residue or transported upwards in a tonalitic liquid. Whereas H<sub>2</sub>O may be transported to the surface in an undersaturated tonalite melt without significant reaction with crustal rocks, CO<sub>2</sub> vapour may diffuse upwards flushing water in front of it until either the H<sub>2</sub>O/CO<sub>2</sub> ratio of the vapour becomes too high to remove further H<sub>2</sub>O or the stability field of scapolite is reached.

The geochemistry of magma generation in rising mantle diapirs is not fully understood at present, and the possibility of generating intermediate calc-alkaline liquids in the presence of H<sub>2</sub>O and CO<sub>2</sub> components directly by partial melting of the mantle under a hot spot must be retained as an alternative. CO<sub>2</sub> in the mantle might be expelled during partial melting or at least partially dissolved in the tonalitic liquid. Subsequent freezing of this liquid in the crust could release CO<sub>2</sub> for metamorphism.

Factors in favour of a hot-spot model are:

- (1) Field mapping and mineralogical geothermobarometry of post-Archaeon 'hot-spots' in continental settings: Adirondack Highlands<sup>69</sup>, Wilmington Complex, Delaware<sup>70</sup>, Naxos thermal dome<sup>71</sup> and Massif Central, France<sup>72</sup>. Particularly indicative of a mantle origin for CO<sub>2</sub> is the low <sup>13</sup>C of fluid inclusions from Naxos, in spite of abundance of local limestones. <sup>13</sup>C-poor CO<sub>2</sub> of present-day carbonic acid springs in tectonic regions is attributed to a mantle origin<sup>73</sup>.
- (2) Continental underplating provides a heat source for high-grade metamorphism of the lower crust. For Naxos<sup>71</sup>, a heavy CO<sub>2</sub> influx of 0.06–0.8 rock volume was estimated to provide enough heat to raise the regional blueschist terrain to migmatite grade.
- (3) Compelling evidence for escape of CO<sub>2</sub> from the mantle today.

Some problems with the hot-spot model are:

- (1) Although high CO<sub>2</sub> activity in the upper-mantle plume might be expected to produce some alkaline basalts<sup>52</sup>, these are almost unknown in the Archaeon<sup>39</sup>.
- (2) Ancient tonalities are strongly depleted in heavy rare earths<sup>74</sup>. Explanation in terms of residual garnet is not supported by too low seismic velocity in lowermost crust for abundant garnet, and modest amount of garnet in granulite nodules transported by kimberlites through shields. A proposal<sup>19</sup> that heavy rare earths were depleted by complexing and vapour transport is not supported by experimental evidence on rare-earth partitioning between silicate melt and high-pressure CO<sub>2</sub>-rich fluid<sup>75</sup>. Crystallization of very abundant residual amphibole might alleviate this problem.
- (3) In western Greenland, both the 3,700 Myr Amitsoq and 2,900 Myr Nûk tonalites were partly metamorphosed into the granulite facies, and it is not clear how a single mantle reservoir could achieve this: however, continental drift and mantle convection might bring a second reservoir into position.
- (4) No explanation is given for strong horizontal tectonic movements during emplacement of tonalite gneisses (for example, Amitsoq and Nûk gneisses<sup>76</sup>).

## Plate-tectonic model

The margin of an Archaeon proto-continent (Fig. 2) consists of a magmatic arc coupled with a back-arc basin. A batholithic root becomes a high-grade granulitic belt after carbonic metamorphism, and basalts and graywacke detritus of the back-arc basin ultimately collapse into a greenstone belt as the island arc coalesces onto continental foreland<sup>77</sup>. Altered oceanic basalts and sediments rich in H<sub>2</sub>O and CO<sub>2</sub> undergo dehydration and

**Fig. 2** Asymmetric plate-tectonic model for crustal growth and carbonic metamorphism. Subsequent compression converts the back-arc basin into a greenstone belt while the magmatic arc undergoes horizontal deformation to produce a high-grade region. Repeated under-riding of the subducted slab and coalescence of each back-arc basin and magmatic arc produces a complex terrain of greenstone belts and high-grade suites. In the subducted slab, dehydration occurs by loss of either a vapour or a liquid phase which passes into the mantle wedge. Some carbonate may survive with eclogite to become mixed mechanically with depleted peridotite. The volatiles from the descending slab interact with carbonate-mica peridotite in the mantle wedge to basaltic magma which mostly crystallizes in the base of the crust where amphibole retains H<sub>2</sub>O. Carbon dioxide is released into a vapour phase which produces a front of patchy granulitization. Remelting of amphibole-rich rocks produces tonalitic magmas which transport H<sub>2</sub>O in the liquid phase to higher levels, leaving a granulitic residue behind. Earlier igneous rocks underwent later carbonic metamorphism.

decarbonation reactions<sup>21</sup> during shallow subduction to produce a devolatilized residue of eclogite with some surviving carbonate<sup>56</sup>. Either magmas or vapours, or both, rise into the mantle wedge carrying mainly H<sub>2</sub>O but with some CO<sub>2</sub>. Heavy arrows indicate corner flow of the mantle wedge<sup>78</sup>, and small arrows indicate melting simultaneously with devolatilization of the subducted slab and possible partial melting therein. The mantle wedge is assumed to provide more CO<sub>2</sub> than H<sub>2</sub>O. Magmas, generally of quartz tholeiite, differentiate in the lower crust, leaving an amphibole-rich residue which retains water and augments rare-earth fractionation caused by residual garnet in the sinking slab. Magma differentiation produces tonalitic plutons and calc-alkaline volcanism. Release of CO<sub>2</sub>-rich vapour in the lower crust, as for the plume model, produces a granulitic lower crust with a front of patchy granulitization. These processes are envisaged to occur quasi-simultaneously but unevenly over ~50 Myr as subduction varies. Finally, when the island arc coalesces with continental foreland, the supply of volatiles from the subducted slab dies away.

The above scheme is tectonically similar to one<sup>79</sup> for Mesozoic calc-alkaline volcanic-plutonic complexes of the western US in which a postulated basaltic underplate is covered by a 10 km granulite layer succeeded by a lower-grade terrain in which crowding of emplaced plutons caused lateral compression. In western Greenland, rising tonalitic plutons became emplaced along active thrust planes<sup>86</sup>.

Alternative mechanisms for calc-alkaline magma generation are by direct melting of oceanic crust in the subduction zone and by direct melting of the overlying mantle wedge. Given the lack of experimental knowledge of melting in mafic and ultramafic systems with mixed H<sub>2</sub>O and CO<sub>2</sub>, and at relatively low pressures, as in a fast shallow convection system, these possibilities cannot be ruled out.

The relative supply of  $H_2O$  and  $CO_2$  is extremely important for success of the plate-tectonic model. Recent mid-ocean basalts tend to absorb more  $H_2O$  than  $CO_2$ , but the most altered ones can contain roughly equal amounts ( $\sim 2$  wt%)<sup>80,81</sup>. Most  $CO_2$  of a subducted slab probably derives from thin calcareous oozes which permeate brecciated basalts as a matrix in the uppermost part of Layer 2<sup>82</sup>. Amphibolitized gabbros of Layer 3 have very little  $CO_2$ <sup>83</sup>. That ancient oceanic basalts may have absorbed more  $CO_2$  than younger ones because of a higher atmospheric pressure is worth exploration. Nevertheless, it seems difficult to obtain a substantial  $CO_2/H_2O$  ratio for a subducting slab, and it seems necessary to appeal to the mantle wedge for the bulk of the  $CO_2$ . Perhaps some carbonate survives in the subducted slab, and augments the mantle reservoir after mechanical mixing with depleted peridotite.

Attractive features of the plate-tectonic model are:

- (1) The general calc-alkaline composition of ancient gneisses is similar to that of the rocks of modern volcanic and batholithic arcs.
- (2) Young back-arc basins compare fairly well in rock types and overall chemistry with greenstone belts<sup>61</sup>. Although some chemical features differ<sup>84</sup>, temporal evolution of the mantle rather than tectonic mechanism may be the principal cause.
- (3) Structural evidence for horizontal tectonics in ancient terrains suggests plate collision.
- (4) Replenishment of  $CO_2$  under continents is provided by 'conveyor belt' action of the mantle wedge associated with the subducted slab.
- (5) Garnet-rich residues mainly in the mantle, coupled with amphibole precipitation in the lower crust, can explain rare-earth fractionation in the tonalitic gneisses.

As with the hot-spot model, unanswered problems exist in the plate tectonics model:

- (1) How can  $CO_2$  remain stored in the mantle during transport under the back-arc basin into the mantle wedge? Should not the  $CO_2$  have escaped with basaltic magmas into the back-arc basin which is supposed to become a greenstone belt?
- (2) How can complex sequences of greenstone belts and intervening high grade gneisses be developed? For the present model the most obvious mechanism is successive coalescence of volcanic arcs onto continental foreland; however, no lateral age variation in greenstone belt sequences has been found<sup>85</sup>, and andesites, the characteristic rocks of modern island arcs, are apparently rare in some ancient greenstone belts (ref. 39).

## Conclusions

It is important to explain the dryness and  $CO_2$ -rich fluid inclusions of ancient high-grade terrains. Because these features occur in very diverse chemical compositions inherited from igneous and sedimentary parents, a metamorphic process is indicated. Experimental phase-equilibria require removal of  $H_2O$  from hydroxylated minerals in the lower crust ( $\sim 20$ – $40$ -km depth) by a vapour with high  $CO_2/H_2O$ . Consequently carbonic metamorphism deserves detailed consideration. The volume of lower continental crust is so great, and the required ratio of  $CO_2/H_2O$  is so high, that a mantle source of  $CO_2$  may be required. Carbonate-bearing peridotite is stable to higher temperature than mica-bearing peridotite deeper than  $\sim 100$  km, and oxidation of carbon might provide another source of  $CO_2$ . Rising basaltic magma containing both  $CO_2$  and  $H_2O$  in solution should lose  $CO_2$  to the vapour phase as the pressure falls below 20 kbar ( $\sim 75$ -km depth) while water can be retained either in magma or in crystallizing amphibole. It is assumed that rising  $CO_2$  vapour will diffuse through rocks containing hydroxylated minerals and flush out the water to produce a residue of dry granulite until the vapour becomes too diluted in  $H_2O$ , or until  $CO_2$  becomes captured by scapolite. Water trapped in amphibole in deep-crustal basalt may subsequently escape to the surface dissolved in remelted diapirs which undergo little reaction with existing rocks.

Because of the complexity of tectonic processes in the Archaean era before development of large continental masses,

there is unresolved speculation about the origin and development of high-grade regions and greenstone belts. Two simple models based on hot-spot and plate-tectonic features show how the concepts of carbonic metamorphism might be applied. Neither is fully satisfactory, but the models may prove useful for further discussion of Archaean geology.

We thank A. T. Anderson, R. A. Howie and P. J. Wyllie for helpful criticisms, but their endorsement of the present speculative ideas is not implied. The following grants are acknowledged: NSF EAR 78-15939 (R.C.N.), EAR 79-05723 (R.C.N.), and EAR 77-21700 (J.V.S.), NASA 14-001-171 (J.V.S.) and NERC GR3/3198 (B.F.W.). We thank S. Moorbath, P. R. A. Wells, G. N. Hanson and D. H. Eggler for their helpful comments.

*During the intertropical cold dry phase from ~20,000 to 12,500 yr BP, the aggrading Nile was a braided, highly seasonal river. With a headwaters change to warmer, wetter conditions, it became an incised, sinuous, suspended load river. Overflow from Lake Victoria and severe floods in Egypt heralded the change in Nile regime.*

THE Nile dominates the northeastern quadrant of Africa, flowing 6,700 km from the glaciated highlands and montane forests of Uganda (4° S) through the alluvial plains and desert sands of Sudan and Egypt into the eastern Mediterranean (31° N, Fig. 1). Recently dated river and lake deposits in Sudan<sup>1</sup>, Ethiopia<sup>2</sup> and Uganda<sup>3</sup>, and eastern Mediterranean deep-sea core data<sup>4–6</sup> now allow us to present an integrated history for the entire Nile basin for the past 20,000 yr. It is now possible to reconcile the alluvial history of the main Nile<sup>7,8</sup> with events in the rest of the basin<sup>9</sup>. We focus on the late Pleistocene dry phase (~20,000–12,500 BP) and the terminal Pleistocene to mid-Holocene moister interval (~12,500–5,000 yr BP). As these two intervals contrast strongly in climate, a coherent interpretation of former Nile regime must accommodate both.

## Nile hydrology and headwaters

Key aspects of the present Nile hydrology<sup>10,11</sup> are shown in Table 1. During the dry winter the White Nile provides 83% of main Nile flow and sustains it to the sea when the Blue Nile has fallen 15 m and the Atbara is dry. During the Ethiopian summer floods Blue Nile flow and suspended sediment concentration<sup>12</sup> increase 40-fold. The Blue Nile and Atbara then provide 90% of the flow and 96% of the sediment of the main Nile. Throughout the late Quaternary, the separate contributions of the White Nile and of the Ethiopian tributaries have to be borne in mind.

Of the two major lakes in the upper White Nile basin, Lake Victoria (Fig. 2) was without outlet for at least 2,000 yr before 12,500 yr BP and probably again, briefly, around 10,000 yr BP (ref. 13), but is unlikely to have dried out completely. Closure of Lake Victoria would have reduced White Nile flow and increased its seasonality. Lake Mobutu Sese Seko (Lake Albert) was closed from ~25,000 to 18,000 yr BP and from 14,000 to 12,500 yr BP (ref. 14), during closure of Lake Victoria. Except for these times, it communicated with the White Nile, maintaining winter flow.

Ruwenzori supported the second largest late Pleistocene ice cap in Africa (260 km<sup>2</sup>). Glaciers also developed on Mounts Kenya, Kilimanjaro, Elgon and the Aberdares. Estimates of mean snowline lowering on each mountain range from >480 to 880 m, corresponding to a temperature decrease<sup>15,16</sup> of 3–6 °C if precipitation remained constant. In Lake Mobutu the diatom

flora suggests cooler conditions<sup>17</sup> than today between 28,000 and 25,000 yr BP. If glacial maximum coincided with the minimum level of Lake Mobutu (25,000–18,000 yr BP), and rainfall was decreased by 25%, a temperature lowering of 6–8 °C would be likely<sup>3</sup>.

Pollen spectra from sites in East Africa point to a colder, drier climate than today between ~26,000 and 12,500 yr BP with highland assemblages dominated by small tree, shrub and grass pollen, indicative of widespread suppression of forest trees<sup>3,18</sup>, and a vegetation more open than it is now<sup>19–21</sup>. Cores from Lake Victoria<sup>13</sup> show that lowland forest was either absent or of very limited extent in the White Nile headwaters between 15,000 and 12,000 yr BP. From 12,000 yr BP onwards equatorial and montane forest spread at the expense of grassland and woodland<sup>3,18</sup>, presumably indicating warmer and moister conditions. Lake fluctuations between 26,000 and 12,500 yr BP were apparently more complex in equatorial Africa<sup>22</sup> than in Ethiopia, and the overflow of Lake Mobutu<sup>14</sup> between 18,000 and 14,000 yr BP suggests that glacial aridity here was less prolonged or severe.

The Atbara, Blue Nile and Sobat originate in the Ethiopian highlands (Fig. 1). Although little is known about the history of Lake Tana on the Blue Nile several lake basins in the Ethiopian and Afar Rifts adjacent to the Ethiopian highlands have been studied in detail, including Lake Abhe<sup>3</sup> and the Rift lakes south of Addis Ababa<sup>9</sup> (Fig. 1).

Lake Abhe, the terminal lake of the Awash River, fluctuates in response to hydrological changes on the eastern margin of the Ethiopian plateau as well as in the Afar depression. Lake Abhe was very high several times during the late Pleistocene and also

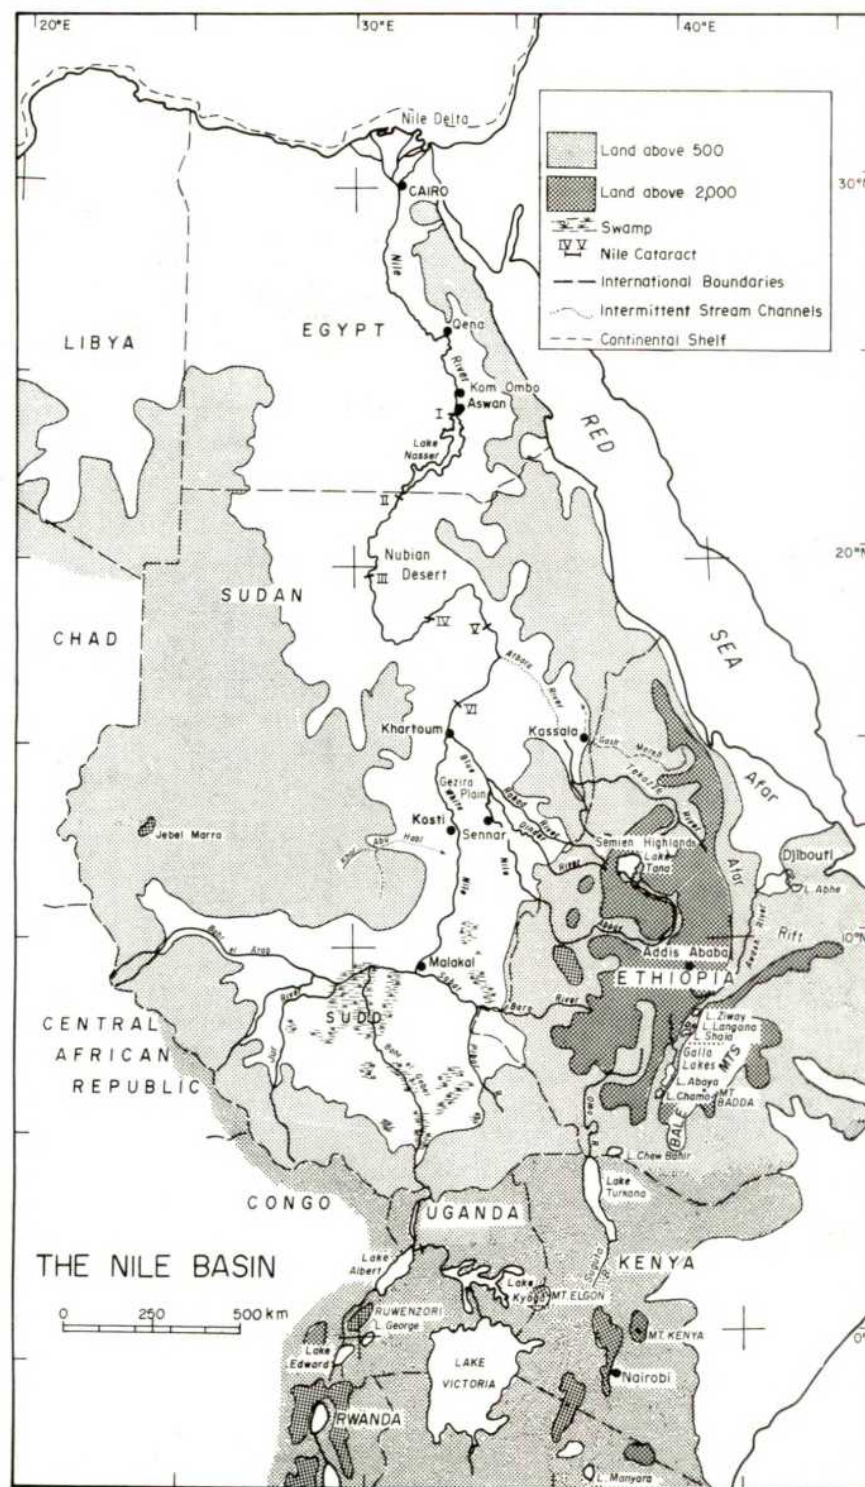

Fig. 1 The Nile basin.

during the early and mid-Holocene but dry from ~17,000 to 10,000 yr BP (Fig. 2). Individual highstands were characterized by quite distinct diatom assemblages and sedimentary facies<sup>9,23,24</sup>, reflecting long-term variations in lake-water chemistry and sediment supply.

The history of the Ziway-Shala basin in the Ethiopian rift (Fig. 1) parallels that of Lake Abhe from at least 30,000 yr BP except that the late Pleistocene lake phases were apparently shorter and less stable<sup>9,25</sup>.

Further south, the Ethiopian plateau drains to the Turkana basin. Since 10,000 yr BP, the fluctuations of Lake Turkana<sup>26-28</sup>

compare closely with those of Lake Ziway-Shala, except for a peak, around  $3,250 \pm 150$  yr BP, which is not evident in the Ethiopian record (Fig. 2). During the early and mid-Holocene, Lake Turkana may have received the overflow from Lakes Chew Bahir<sup>29</sup>, Chalbi (D. Phillipson, personal communication) and, possibly, Suguta<sup>30-32</sup>. It overflowed NNW into the Pibor-Sobat (White Nile) system from ~9,900 to 7,900 yr BP and possibly also between 6,600 and 3,250 yr BP (refs 26-28).

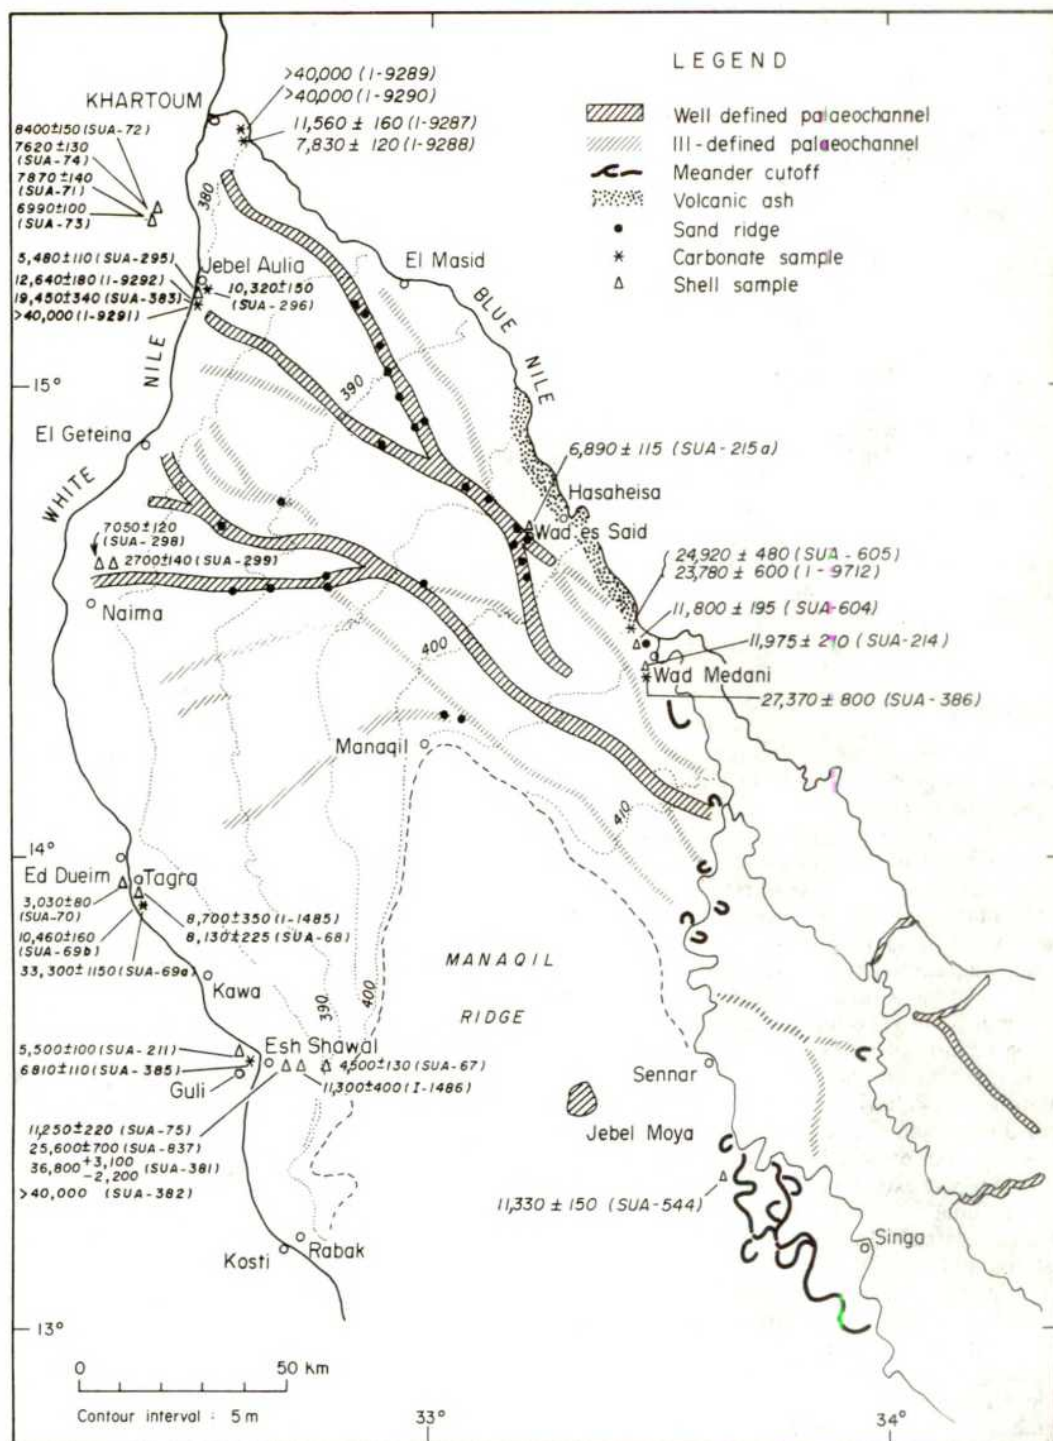

The fluctuations of these lakes stem from variations in water balance resulting from changes in climate. The latter were also reflected in variations in snowlines, vegetation cover, and slope

**Fig. 3** The Blue and White Nile rivers, central Sudan, showing location of dated sites. Field mapping based on over 500 2-m boreholes and trenches.

The extension of closed vegetation types during the early Holocene was reflected in widespread slope stabilization in both highland and lowland areas. Consequently, the rivers transported predominantly fine-grained sediments and the clastic influx into the lakes was reduced by comparison with the preceding period. For example, the Meki River, which enters Lake Ziway from Ethiopian escarpment, began to lay down fine alluvial loams instead of coarse gravels.

We conclude that the phases of highest sediment yield from the Ethiopian highlands and lowlands corresponded to times of maximum aridity, minimum water yield, and highly seasonal runoff during the very cold late Pleistocene interval. These conditions dominated the fluvial regimes of the Blue Nile and Atbara rivers during the late Pleistocene arid period. In contrast, the terminal Pleistocene to mid Holocene was moister, the vegetation cover was more complete, slopes more stable, and sediment yield reduced.

### Alluvial plains of the central Sudan

The alluvial plains of the lower Blue and White Nile rivers in central Sudan provide a depositional legacy of erosional events in their respective catchments<sup>42-44</sup>. A vast low-angle alluvial fan (the Gezira fan), up to 200 m thick and over 200 km in radius<sup>1</sup>, was built up during the past 20 Myr (ref. 45) by ancient Blue Nile distributaries as they emerged from the Ethiopian highlands onto the plains of the Sudan. Our concern here is with the upper 4-5 m of this fan, which contains late Quaternary sediments from the two Niles (Fig. 3).

During a long interval dated<sup>1,46</sup> at  $>40,000$ -25,000 yr BP evaporite deposits of microcrystalline dolomite and calcite accumulated along the White Nile near Esh Shawal. River sands which became progressively more clay-rich were laid down over the evaporites, and were in part reworked by wind to form dunes<sup>1,46</sup> which were later flooded by the White Nile towards 12,000-11,000 yr BP. Radiocarbon ages of unbroken fresh-

water and amphibious mollusca indicate high White Nile flood levels towards 12,500–11,400, 8,400–8,100, 7,000, 5,500, 3,000–2,700, and 2,000–1,500 yr BP (Figs 2, 4). Excavations at Shabona<sup>47,48</sup>, where small groups of elephant, buffalo and hippo hunters camped on low fixed dunes overlooking flooded White Nile swamps from which they collected abundant *Pila* snails dated to 7,000 yr BP confirmed that the White Nile floods were high towards 8,000–7,000 yr BP.

Figure 4 shows that high Blue Nile flood levels tally in detail with those of the White Nile for the intervals 12,000–11,000, 8,000, 7,000 and 5,500 yr BP. There is no evidence of extensive Blue Nile flooding in central Sudan after about 5,500 yr BP when the river entrenched some 10 m into its former floodplain<sup>49–51</sup>. The dated Blue Nile high flood levels coincide with early to mid-Holocene high lake levels and higher water-tables in Ethiopia<sup>2,9,23,52</sup>, with small lakes at En Nahud in Kordofan (6,800 yr BP)<sup>1</sup> and in Wad Mansurab basin 13 km north-west of Jebel Aulia<sup>53</sup> (Fig. 3) (8,400–7,000 yr BP).

Cross-bedded sands and gravels underlie the Blue Nile Holocene clays and occupy channel-fills within them. Borehole data reveal a change from a low-sinuosity bed-load regime to a high-sinuosity mixed- or suspended-load regime towards 12,000–11,000 yr BP (refs 1, 44), coinciding with forest expansion and slope stabilization in the Blue Nile headwaters.

## Main Nile

The intricate response of different parts of the Nile basin to climatic change<sup>7,8,54–56</sup> was first shown by studies of the alluvial stratigraphy of Upper Egypt and Nubia<sup>7</sup>. Here, Nilotic formations of late Quaternary age (Fig. 2) interfinger with local dune, wadi and pond deposits. Phases of aggradation by the main Nile were separated by episodes of rapid downcutting.

The oldest unit, the Korosko Formation<sup>7</sup>, consists of marls, gravelly marls, sandy gravels and Ethiopian silts deposited by a rapidly aggrading, braided Nile which was actively fed by local wadis. A probable minimum age of 27,250 yr BP has come from the upper part of this formation<sup>7,8</sup>.

Aggradation of the Masmas Formation<sup>7</sup> began long before 21,000 yr BP, and ended<sup>8</sup> around 18,000 yr BP. The deposits comprise thick, horizontal flood silts of Ethiopian origin with occasional channel sands. They were laid down on a floodplain more than three times broader than today. Frequent crevasse splays suggest extensive seasonal flooding. Contemporary aridity in Nubia<sup>7,8,55,56</sup> is indicated by dunes lining the west bank, which are dated<sup>57,58</sup> at 19,000–17,000 yr BP. Local wadi activity was minimal.

During the Darau substage of the Gebel Silsila Formation<sup>7</sup> (17,000–12,000 yr BP) vigorous braided channels existed on a floodplain twice as wide as today depositing a mixture of sands, gravels and Ethiopian flood silts. Exotic pebbles in the Darau Member as well as further upstream in Blue Nile deposits imply significant fluvial transport from Ethiopia and Sudan. At this time in Nubia and upper Egypt the wadis were intermittently active during the period 17,500–12,000 yr BP<sup>7,8</sup> and pollen and diatom assemblages from permanent ponds indicate a locally cooler and effectively more humid climate than today. The Darau substage ended in a period of exceptionally high floods<sup>8</sup> around 12,000–11,500 yr BP. Recent dates suggest that aggradation of mainly Ethiopian silts took place in the terminal Pleistocene to mid-Holocene intervals 11,200–9,300, 8,000–7,000 and 5,800–5,400 yr BP, with particularly high levels around 7,100 yr BP. Wadi deposits in Nubia indicate several phases of enhanced local runoff between ~11,500 and 5,000 yr BP. From 5,000 yr BP onwards, however, conditions in both Egypt and Nubia became increasingly arid<sup>7,8</sup>.

## Nile cone and eastern Mediterranean

Stratigraphic and isotopic evidence<sup>4–6</sup> from eastern Mediterranean cores now allows partial separation of the effects of changes in river regime and sediment discharge<sup>8,54,59</sup>.

Three recently recognized Nile cone cyclothem<sup>4,5</sup> dated at 58,000–28,000, 28,000–17,000 and 17,000–0 yr BP are broadly coeval with the three alluvial formations in Nubia<sup>8</sup>. Each cyclothem comprises a sapropel unit, muds and turbidites, and a calcareous unit. The three sapropels coincide in time with high lake levels in the Nile basin<sup>9</sup> and Arabia<sup>60</sup>, and with the deposition of Ethiopian silts in central Sudan<sup>1</sup> and Egypt<sup>8,59</sup> (Fig. 2). Sapropel 1 (9,000–7,000 yr BP) also corresponds with the early

**Fig. 4** Dated high Blue and White Nile flood levels in central Sudan. (All ages are corrected for isotopic fractionation; circles are pedogenic carbonates; dots are shells; bars represent 2 standard deviations.)

Holocene expansion of forest in the Nile headwaters<sup>3</sup>. The sapropels reflect stagnation of deep ocean water arising from a major influx of freshwater<sup>6</sup> into the eastern Mediterranean from such sources as the Nile and Black Sea<sup>61,62</sup>. The isotopic change evident towards 9,000–7,000 yr BP in core GA32 is best attributed to both a temperature increase and a freshwater influx<sup>6,61</sup>. The periods of calcareous ooze accumulation<sup>4,5</sup> correspond to times of aridity in the Nile basin. Stable isotope measurements in deep-sea cores from the eastern Mediterranean suggest that at the last glacial maximum, as at present, the eastern Mediterranean had an excess of evaporation over combined precipitation and river input (N. J. Shackleton, personal communication).

Evidence both from the eastern Mediterranean sea floor and from the Nile basin shows that in this region the interval 12,000–5,000 yr BP was generally moister than today and far wetter and warmer than the preceding late Pleistocene phase. Certain inferences may now be drawn about the late Quaternary Nile.

## The 20,000–12,500 yr BP Nile

Cold dry conditions in the headwaters<sup>1–3,36</sup> had profound effects on water and sediment supply to the Nile. Reduced vegetation cover, periglacial processes and summer snow melt gave heavy loads of coarse sediment. Flood peaks were high, annual discharge low. Episodic closure of the headwater lakes<sup>13,14</sup> and consequent reduction in the area of swamps accentuated the seasonality of flow. The White Nile became a seasonal, intermittent river. Annual discharge from the Ethiopian headwaters diminished, so that flow along the main Nile was severely curtailed.

Along the lower White Nile bedload sands were reworked into aeolian dunes during the dry season<sup>46</sup>. Distributaries of the Blue Nile radiated across the Gezira, also furnishing bedload sand for dune formation<sup>63</sup>. The Atbara was even more intermittent than today. Summer floods were substantial, braided distributaries of the Blue Nile and Atbara spread fine gravels (including agate and chalcedony), sands and silts across their alluvial fans. Braided stream channels were characteristic of the main Nile in Egypt and Sudanese Nubia<sup>8</sup>, where mixed sediments similar to those upstream were also deposited. The sharing of flow among braided channels implies that the bedload was moved less efficiently than if flow were concentrated into one or two channels, with minimal frictional loss of stream energy. As flow ceased in the dry season bedload was locally reworked by wind. Channel instability was common during the flood seasons.

## The 12,500–5,000 yr BP Nile

Following overflow from the headwater lakes and rapid expansion of swamps in southern Sudan, Nile flow became permanent and more regular. In the immediate aftermath of overflow from Lake Victoria towards 12,500 yr BP, there was major flooding along the White Nile<sup>1</sup>. Full buffering by the Sudd swamps had not yet developed, so that vast quantities of water were released into the main Nile. The Blue Nile and Atbara also discharged high floods as rainfall increased in Ethiopia at this time. This

helps to explain the few centuries of extremely high floods<sup>8</sup> in Egypt.

Thereafter permanent flow and much reduced seasonal fluctuation allowed the Nile to move its bedload along one or a few dominant channels. Regular Blue Nile floods laid down several metres of clay in the swampy plains of the Sudan Gezira<sup>63,64</sup> and overbank floods deposited the Arminna/Kibdi silts on the narrow Egyptian floodplain<sup>8</sup>.

## Conclusion

The fluvial response of the Nile to late Quaternary climatic changes in the headwaters helps to explain why rivers sometimes aggrade and sometimes degrade their floodplains. Between 20,000 and 12,000 yr BP when timberline in the headwaters was lower and the vegetation cover more open than today, the Nile was a highly seasonal braided river which brought mixed coarse and fine sediments down to Egypt and Sudan. This cold, dry interval had ended by 12,500 yr BP when overflow from Lake Victoria and higher rainfall in Ethiopia sent extraordinary floods down the main Nile, marking a revolutionary change to continuous flow with a superimposed flood peak. The main Nile and its tributaries established more stable channels of higher sinuosity, from which suspended Ethiopian silt and clay was deposited on the floodplains. The Blue Nile began to cut down, thereby depriving the Gezira fan of flood waters. By the mid-Holocene, the modern era of the Nile had begun.

Evidence from earlier periods is consistent with the above interpretation of the relation between Nile behaviour and environmental conditions in the basin (Fig. 2). The thick sequence of evaporite deposits and saline sediments on the lower White Nile also suggest earlier periods of desiccation and intermittent river flow which must have affected the main Nile. Study of the sediments beneath the Sudd and of the little known White Nile evaporites is required for the light they will shed on the earlier history of the basin.

We thank P. Goldberg, J. G. Jones and R. J. Wasson for discussions.

# Integration of visual and auditory space in the mammalian superior colliculus

Laurence R. Harris\*, Colin Blakemore† & Michael Donaghy‡

The Physiological and Psychological Laboratories, University of Cambridge, Cambridge CB2 3EG, UK

*Recordings of eye movements and single-neurone microelectrode recordings of the superior colliculus in cats show that, for each saccadic movement, their eyes start near to the centre of the orbit so that the coordinates of visual and auditory space are aligned, and complex neural compensation of auditory or visual inputs to the superior colliculus is unnecessary.*

EYES and ears are specialized for detecting events at a distance. Both vision and hearing can be used to localize objects in external space—a function of utmost importance to any animal anxious to avoid its predators or discover its prey. One part of the brain, the midbrain tectum (which in mammals consists of the superior and inferior colliculi), seems especially concerned with the analysis of spatial information derived from both the eyes and the ears. In animals of diverse phylogeny<sup>1–6</sup> there are neurones in the midbrain that have spatially restricted receptive fields in auditory or visual space and which respond when a sound or light stimulus appears (or preferably moves) within the appropriate, limited region of space. These systems of sensory neurones are topographically organized to form neural ‘maps’ of auditory and visual space across the midbrain tectum.

The idea that the roof of the midbrain is devoted to the analysis of positional information in external space is supported by the existence there in some species of other mechanisms for localization. The superior colliculus (SC) of cats<sup>7</sup>, mice<sup>4</sup> and hamsters<sup>8</sup>, as well as having both visual and auditory input, has a topographical representation of the body surface including the whiskers; neurones in the inferior colliculus of the bat<sup>9</sup> may play a part in echo location; and in the SC of the viper there is even a spatial representation of signals from the IR pit organs in the snake’s face<sup>10</sup>.

Damage to the tectum interferes with an animal’s ability to ‘orient’ towards stimuli: indeed, lesions of the hamster’s SC produce a visual defect that renders the animal seemingly blind to novel events in its visual field<sup>11</sup>. In the cat, removal of one SC (which represents primarily the opposite half of space) produces neglect of the contralateral hemifields<sup>12</sup>. Also, lesions of the colliculus in monkeys cause deficits in the timing of eye movements<sup>13</sup>.

Further evidence for the importance of the SC in initiating orienting movements towards sounds or sights comes from the fact that electrical stimulation of this structure in unanaesthetized animals elicits movements of the eyes, head, ears and body towards the opposite side of space<sup>14,15</sup>.

## Correspondence of visual and auditory representations in the superior colliculus

The integrity of the perceptual world clearly demands correlation of positional signals from all sensory systems and especially of messages from the eyes and ears. An animal must know that an object that it both sees and hears is a single thing at one place in space; responses initiated by either auditory or visual cues must be harmonized and coordinated.

The deep layers of the mammalian SC seem ideally equipped for the correlation of spatial cues from the eyes and ears,

for here there are superimposed auditory and visual representations<sup>7,8,16–18</sup>. Neurones in the rostral part of the SC respond to sounds or sights directly in front of the animal, whereas for those further back, visual and auditory receptive fields are shifted into the contralateral hemifield of space. Indeed in cats, many individual cells receive both auditory and visual input<sup>16</sup>: the activity of such neurones could be thought of as providing pure, positional information regardless of the sensory channel mediating it.

In support of this concept, Wickelgren<sup>16</sup>, working on the deep layers of the SC in paralysed cats, found such bimodal cells to have their visual and auditory receptive fields (though large) well matched in their horizontal eccentricity in space. Each neurone responded to either a spot of light or a small sound source presented in one particular region of the field. Could such cells in the cat’s SC be responsible for the functional integration of visual and auditory space, triggering orienting movements towards peripheral objects whether identified by their visual appearance or by the noise they make?

## The effect of eye movements: Pöppel’s paradox

This hypothesis, though attractive in its simplicity, is paradoxical. Cells are able to respond selectively to sounds at a particular position by using the relative timing or intensity of sound at the two ears as the cue to direction: the coordinates of auditory space are defined with respect to the ears and hence the head. The positions of visual receptive fields are, however, defined with respect to the retina. As the eyes can move in their orbits, the coordinates of visual and auditory space used by bimodal neurones should, as Pöppel<sup>19</sup> has pointed out, be torn apart every time an eye movement occurs. Unless some compensatory process occurs, bimodal neurones in the SC should provide ambiguous directional information whenever the eyes are deviated from the straight-ahead position.

There are at least three possible ways in which each bimodal collicular cell might take account of changes in eye position: (1) The cell’s visual receptive field might move with respect to retinal coordinates by an angular distance equal and opposite to each eye movement, thus maintaining spatial correspondence with the auditory receptive field. (2) The cell’s auditory receptive field might move in space by an amount equal to each eye movement and in the same direction, to preserve the correspondence. (3) The auditory or visual input to the cell might simply be switched off whenever the eyes are significantly deviated from the central position, at which the auditory and visual receptive fields are aligned.

The first two possibilities seem implausible because they demand rapid and gross reorganization of the connections between the eyes or the ears and the SC each time the eyes move. The third hypothesis, which was not considered by Pöppel, is perhaps somewhat more likely. We have now examined this perplexing problem in alert cats.

**Fig. 1** The auditory and visual receptive fields of bimodal cells in the deep layers of the SC are roughly superimposed in space. The inset shows the recording sites (○) of 27 bimodal cells reconstructed with respect to electrolytic lesions and projected on to the horizontal stereotaxic plane within the outline of the right SC. The graph shows the azimuth angle of the centre of the auditory receptive field plotted against that of the visual receptive field for all 22 of the neurones that responded well to the stationary tone used to plot the auditory field. The cat's eyes were centred in the orbits and the head was fixed in the straight-ahead position. For six cells the horizontal extents of the visual and auditory receptive fields are indicated by horizontal (visual) and vertical (auditory) lines.

### Testing the three hypotheses

For three adult female cats we used the techniques of Evarts<sup>20</sup> and Schiller and his collaborators<sup>21</sup> to implant silver-silver chloride electrodes<sup>22</sup> around the eyes (for recording horizontal and vertical eye movements electro-oculographically) and a chamber above the SC (for the introduction of glass-coated tungsten microelectrodes to record from single neurones).

We trained each animal to accept being wrapped in a cloth bag and to lie inside a padded box. Its head protruded through a large aperture and was attached to a superstructure that could be used either to measure horizontal and vertical head movements<sup>23</sup> or to fix the head in one position. With training the cats soon accepted these procedures.

To stimulate cells visually, a spot of light was back-projected on a translucent hemisphere (radius 57 cm) placed directly in front of the cat. Auditory receptive fields were plotted quantitatively by measuring the responses of cells to quiet tone bursts (duration 225 ms, frequency 1.2 Hz) emitted from a small radio earphone suspended from a crane whose centre of rotation was co-axial with the cat's head and whose angular position was varied in 10° steps over 180° in front of the cat and monitored by a potentiometer. The electro-oculogram (EOG) was calibrated<sup>15,24</sup> and the position of the eyes was monitored as a two-dimensional display on a storage oscilloscope. For subsequent computer analysis, horizontal and vertical EOG signals were recorded on tape, together with the neurone's action potentials, the voltage corresponding to the position of the auditory stimulus and pulses to indicate each onset of the sound.

### Precision of correspondence of visual and auditory receptive fields

We studied 27 bimodal cells (giving responses of roughly similar strength to optimal visual and auditory stimulation) in the deep layers of the SC. 50% of the cells recorded in the colliculus

below 1.2 mm from the surface were bimodal. The inset in Fig. 1 shows the position of each recording site at which a bimodal cell was found. With the cat's head held in the straight-ahead position, her attention was constantly attracted to the centre of the hemisphere, and fixation at the centre was constantly checked from the two-dimensional display of eye position. The position of the visual receptive field of the neurone was plotted by monitoring the responses elicited by a small moving spot (~2° in diameter) back-projected on to the hemisphere. Then the hemisphere was removed, all the room lights extinguished and the horizontal extent of the auditory receptive field plotted out by setting the height of the small loudspeaker on the same level as the middle of the visual receptive field, swinging the crane to various positions in front of the cat's head and recording the responses to tone bursts. Only five of the 27 bimodal cells could not be studied in this way because they failed to respond to the pure tone and were excitable only by more complex sounds such as key-jingling or finger-snapping.

Eye position was constantly monitored throughout this procedure. Rapid recalibration of the EOG, by the simple procedure<sup>15</sup> of examining the range of signals produced as the cat made eye movements over the whole oculomotor range, showed little change in the d.c. level or gain of the EOG within the period of darkness in these experiments.

All bimodal cells were spatially selective in their responses to sound and visual stimuli, although in some cases, especially for cells in the more caudal part of the colliculus, representing the more peripheral field, visual and auditory receptive fields were rather large and their borders not sharply defined. However, we were satisfied that our data confirmed Wickelgren's<sup>16</sup> observation that, with the eyes in a straight-ahead position, visual and auditory receptive fields are quite well aligned and usually of about the same horizontal extent. The graph in Fig. 1 plots the horizontal position of the centre of the auditory receptive field against that of the centre of the visual receptive field: total horizontal extents are also indicated for six typical cells.

### Is there compensation of the visual receptive field during eye movement?

We did not attempt to measure possible minor variations in the dimensions, sensitivity or retinal positions of the visual receptive fields of bimodal cells during deviation of the eyes. However, for a number of bimodal cells we did informally replot the visual receptive field while attracting the animal's attention to various points on the hemisphere and hence producing deviation of the

**Fig. 2** A sample record from the experiment in which tone-burst stimuli were presented in the dark while the head was held. The position of the tone was randomized and the animal was encouraged to move her eyes. The top trace represents the horizontal eye position (approximate amplitude calibration on the right; interrupted line indicates the centre of the oculomotor range). The second trace shows the position of the crane that carried the loudspeaker (amplitude calibration on the left, with a sketch of the arrangement showing three positions labelled 1, 2 and 3, corresponding to the parts of the trace labelled). The third trace shows the duration of each 1.2 kHz tone burst (duration 225 ms). The bottom trace is an oscillograph recording of action potentials from a bimodal cell. Movements of the crane and noises produced by the experimenter elicited some activity between test stimuli. Clear responses to the tone are indicated by arrows.

**Fig. 3** Quantitative determinations of the spatial location and extent of the auditory receptive field of a bimodal cell. The visual receptive field for this unit was centred  $\sim 25^\circ$  to the left of the vertical meridian of the visual field. Tone stimuli were presented randomly at different positions in front of the cat with the head held in darkness. The animal was encouraged to deviate her eyes. The response (mean number of impulses in the 500-ms period following the onset of the tone averaged over at least five stimulus presentations) is plotted along the radial axis of the polar graph. The average standard deviation is 2.7 impulses per point. The angle of this polar plot represents the angular horizontal position of the loudspeaker. Data are plotted for three conditions of eye fixation: eyes centred (within  $7^\circ$  of straight ahead;  $\circ$ ), eyes deviated more than  $7^\circ$  right ( $\square$ ) or left ( $\bullet$ ). The auditory receptive field seems to be unchanged in spatial position and in sensitivity during deviation of the eyes.

eyes away from the central position. In no case was there any evidence of an obvious change in the retinal position of the receptive field: it always moved with the eyes and, except for possible brief changes in sensitivity associated with saccadic movements themselves<sup>15,25</sup>, no bimodal cells seemed to suffer dramatic reduction in visual sensitivity during deviated gaze. We therefore reject the first hypothesis described above, as well as the possibility of strong attenuation of the visual input during deviated gaze (hypothesis (3)).

### Is there compensation of the auditory receptive field during eye movement?

To test the second hypothesis we performed a detailed quantitative experiment on three bimodal cells (though the result was confirmed informally on many more). For each cell a series of  $\sim 500$  auditory stimuli was delivered in total darkness with the cat's head held straight ahead and with the position of the crane randomly varied from tone to tone. We took care to deliver tones only when the crane was stationary and the room silent. In addition, between tone stimuli, the cat's attention was frequently attracted by tapping or speaking to persuade her to deviate her gaze away from the straight-ahead position. A commentary on the progress of the experiment was made on the voice channel of the tape recorder. Thus we randomized the position of controlled auditory stimuli while the eyes were sometimes straight ahead, sometimes deviated right, sometimes left.

Figure 2 is a typical example of the records obtained, showing eye position, crane position, sound stimuli and the activity of the cell. Note that although the cell was frequently active between the tone stimuli, in response to the relatively loud attention-attracting noises, only two of the tone bursts (marked with arrows) elicited clear responses.

In an off-line computer analysis, the responses of the neurone to tones at each position in auditory space were averaged for three ranges of gaze position: eyes straight ahead (within  $7^\circ$  of the resting position); eyes deviated  $>7^\circ$  right of centre; eyes deviated  $>7^\circ$  left. The data available allowed at least five responses to be averaged for every stimulus condition.

Figure 3 shows the results for one bimodal cell that had its visual receptive field centred about  $25^\circ$  left of the midline. Each point represents the average number of impulses in a 500-ms interval following the onset of the tone. Points are plotted on polar coordinates, the radial axis indicating the magnitude of the response. The data collected within each of the three ranges of gaze position are plotted with different symbols and clearly the maximum response was always of about the same magnitude and always occurred with the loudspeaker placed  $\sim 25^\circ$  to the left of the midline, whatever the position of the eyes. The auditory receptive field did not move with the eyes, neither was the auditory input switched off when gaze was deviated. This result, which was reproduced in two other cells whose receptive fields were centred about  $45^\circ$  and  $70^\circ$  from the midline, seems to eliminate the remaining hypothetical forms of compensation described above.

For some cells the auditory receptive field was replotted with the head fixed not straight ahead but at a  $45^\circ$  angle to the right or left with respect to the body axis. In all cases the auditory receptive field shifted by precisely the same angle as the head. The auditory receptive field seems locked to head-centred coordinates, as one would expect if it depends on timing or intensity differences at the ears for its spatial selectivity. The auditory receptive field is not fixed with respect to the eyes nor with respect to the body axis as it does not move with the eyes when the head is stationary and it does move with the head when the head moves.

### Recentring of the eyes during gaze shifts

Our results so far indicate that there is no simple mechanism in the cat's SC for compensating for deviations of the eyes. Indeed, we predict that cats might suffer perceptual misalignment of visual and auditory space when the eyes are fixating peripherally. However, further experiments have revealed that a simple motor strategy ensures that this situation very rarely occurs in normal, freely moving cats.

**Fig. 4** Records of natural horizontal eye-in-orbit movements (E) and head movements (H) as a cat looks around a well lit stationary scene, in three conditions. The vertical calibration for each trace shows  $\pm 20^\circ$  deviation from the straight-ahead position, which is indicated by an interrupted line. *a*, Head held stationary. The eyes make a series of characteristic saccades with intervening fixations, lasting up to  $\sim 2$  s, with the eyes deviated up to  $\sim 30^\circ$  from the centre of the orbit. *b*, Head free to move in the head-holder, which transduces head movements but impedes and slows them a little. Now each large eye saccade is accompanied by a head movement in the same direction. The vestibulo-ocular reflex evoked by each head movement results in a compensatory counter-rotation of the eyes, tending to bring them back towards the centre of the orbit. *c*, Head completely unrestrained (hence no trace for head position). Recentring of the eyes after each saccade is now even more efficient, indicating that the head usually executes a movement almost equal in amplitude to that of the eyes. Hence each new change of gaze starts with the eyes near the centre of the orbit.

In these three animals, and in three other cats implanted for EOG recording and head fixation, we used the methods of Blakemore and Donaghy<sup>23,24</sup> to study coordinated movements of the head and eyes during changes of gaze. The superstructure to which the animal's head was fixed could be released to allow relatively free head movement, the horizontal and vertical rotations of which were monitored through potentiometers attached to the axes of rotation. We measured eye movements as the cat simply looked around the room in three conditions: head held still, head free to move in the headholder, and head completely unrestrained (Fig. 4).

**Fig. 5** Histograms showing the frequency of occurrence of eye-in-orbit position during steady fixation in head-fixed (interrupted line) and head-free (solid line) conditions (compare with Fig. 4a, c). The abscissa shows the horizontal position of the eye in the orbit (rightward and leftward deviations pooled) at the start of each saccade. Efficient recentering of the eyes in the head-free condition results in most new saccades starting with the eyes roughly centred in the orbit.

With the head held still the eyes make typical saccadic movements of up to  $\sim 40^\circ$  amplitude with the eyes being held almost stationary for periods of up to 2 s, at deviations in the orbit of up to  $\sim 30^\circ$  from straight ahead (Fig. 4a).

The situation is different when the head is allowed to move (Fig. 4b, c). Gaze changes of more than a few degrees in amplitude are now accomplished by combined movements of the eyes and head, with the eyes' saccade usually starting 25–50 ms before the start of the head movement<sup>23,24</sup>. Large changes in the direction of gaze involve a staircase of saccadic jerks of the eyes superimposed on a large head movement. Whenever the head is in motion, a counter-rotation of the eyes in the orbit, of opposite direction to the head movement and of virtually identical velocity, is superimposed on whatever other

eye movement is occurring. Blakemore and Donaghy<sup>24</sup> and Donaghy<sup>27</sup> have shown that this counter-rotation of the eyes in cats is due to the accurate operation of the vestibulo-ocular reflex. This has the effect of slowing down the saccade if the head begins to move before the eye has reached its target, and of causing a compensatory eye drift in the direction opposite to the saccade as the head movement continues after the end of the saccade (Fig. 4b). As the head rotation is usually of similar angular displacement to the saccadic eye rotation it accompanies, the net effect is to return the eye close to its starting position shortly after each saccade.

The saccadic mechanism can be viewed as a rapid motor system for the fixation of objects of interest, but the complete gaze change in a cat nearly always involves a similar movement of the head that effectively recentres the eyes. Hence, whenever a cat is steadily fixating an object after a whole gaze change is complete, the eyes are nearly always close to the centre of their orbits. This is very clearly shown in records of horizontal eye position when the head is completely unrestrained (Fig. 4c). Nearly all steady fixations occur with the eye close to the orbital centre, and each new change of gaze starts from roughly the straight-ahead position.

Figure 5 plots as a histogram the horizontal starting positions of the eye in the orbit for 70 successive changes of gaze made by each of two cats as they looked around a stationary scene. With the head fixed, the distribution of starting positions has almost constant probability out to  $20^\circ$  deviation and some saccades started with the eyes deviated horizontally by more than  $30^\circ$ . On the other hand, with the head completely unrestrained more than half of all saccades started with the eyes less than  $3^\circ$  from straight ahead in the orbit and very few started with the eyes more than  $10^\circ$  from the primary position.

## Paradox resolved for the cat, but not for primates

Pöppel's paradox<sup>19</sup> turns out not to be a problem for the cat. Complex neural compensation of the auditory or visual inputs to bimodal cells is unnecessary because the motor programme used by the cat to look around ensures that the eyes rapidly return near to the centre of the orbit after each saccade. Every time a new peripheral object attracts the cat's attention its SC can safely assume that the eyes are near the primary position, and hence that the coordinates of visual and auditory space are aligned.

On the other hand, for primates, including humans, the paradox still remains. Quite clearly, monkeys and people do not follow every eye saccade with a head movement of nearly identical amplitude. Occasionally fixation is maintained steadily on a peripheral target with the eyes deviated by  $40^\circ$  or more. We know very little about the neural basis of sensory integration in monkeys (and even less, of course, in man) although bimodal cells have been described in the primate SC<sup>28,29</sup>. The greater independence of the head movements in primates makes Pöppel's paradox a real issue once again.

# Leaky +1 and -1 frameshift mutations at the same site in a yeast mitochondrial gene

Thomas D. Fox & Brigitte Weiss-Brummer\*

Department of Biochemistry, Biocenter, University of Basel, CH-4056 Basel, Switzerland  
\* Genetisches Institut der Universität München, Maria-Ward Strasse 1a, D-8000 München, FRG

Two mutations in a mitochondrial structural gene, which cause leaky premature polypeptide chain termination and leaky growth, are +1 and -1 frameshifts in the same run of five T residues. The partial restoration of reading frame is probably due to ribosomal frameshifting at this site, and may be promoted by the unique structure of the yeast mitochondrial tRNA<sup>Phe</sup> (ref. 1).

THE mitochondrial genetic system carries out the relatively limited task of making about 10 polypeptides. It has become clear recently that the genetic code specifying these polypeptides is somewhat different from the standard genetic code, and that there are even differences in the code between mitochondria in different species<sup>2-8</sup>. These differences could be due to the ability of mutations that change the code to be tolerated and fixed in a simple genetic system or due to some unknown selection for novelty. They might also reflect some primitive features of the mitochondrial genetic system.

To probe the nature of the mitochondrial genetic system further, we have continued to examine the DNA sequence of mutations in the yeast mitochondrial structural gene termed *oxi-l*, which codes for subunit II of cytochrome *c* oxidase<sup>3,9</sup>. One specific aim of these studies is to investigate the possibility that some codons which do not occur in the wild-type gene might be untranslatable. For this reason we examined several mutations in the *oxi-l* locus that were previously reported<sup>10</sup> to behave like leaky polypeptide chain terminators. Surprisingly, the leaky mutations examined so far have been found to be +1 and -1 frameshift mutations at a particular site in the structural gene. The findings indicate the existence of a mechanism that can promote frequent reading frame errors at specific sites during the expression of yeast mitochondrial genes.

## The leaky phenotype

Among a recently described collection of some 90 *oxi-l* mutants<sup>10</sup>, five mutants were reported to have a leaky growth phenotype on medium containing non-fermentable carbon sources, and to synthesize greatly reduced amounts of cytochrome *c* oxidase subunit II. We have re-examined the phenotype of three of these mutants and have confirmed and extended the previous findings. When streaked on plates containing ethanol and glycerol as carbon sources, the three mutants M5661, M5701 and M5631 (Fig. 1c, e, g, respectively) grew significantly at 30 °C and 37 °C but not at 20 °C. In contrast, a non-leaky mutant (M13-249), shown previously by DNA sequence analysis to carry a frameshift, did not grow at any of these temperatures (Fig. 1b). In addition, spontaneous revertants of each of these mutants (Fig. 1d, f, h) grew similarly to wildtype (Fig. 1a). (Subsequent experiments demonstrated that the mutants M5661 and M5701 were independent isolates carrying identical lesions. Therefore, results are presented below only for M5701 and the third strain M5631.)

To examine the products of mitochondrial translation in these strains, yeast cells were treated with cycloheximide to inhibit cytoplasmic protein synthesis, and then labelled by incubation at 30 °C with <sup>35</sup>SO<sub>4</sub>. Crude mitochondrial fractions were prepared

**Fig. 1** Growth of wild-type, *oxi-l* mutant and revertant yeast strains on medium containing non-fermentable carbon sources. Plates containing 1% yeast extract, 2% peptone, 3% ethanol and 3% glycerol were streaked and incubated for 9 days at the temperatures indicated. The yeast strains were: a, wild type; b, M13-249, a non-leaky frameshift mutant<sup>3,26</sup>; c, M5661; d, a spontaneous revertant of M5661; e, M5701; f, a spontaneous revertant of M5701; g, M5631; h, a spontaneous revertant of M5631. The mutants M5661, M5701 and M5631 were isolated from the haploid *pet<sup>-</sup> (rho<sup>0</sup>)* strain 777-3A (ref. 10). To reveal the growth phenotype of these mitochondrial mutations and the wild type, diploids were formed from these strains by crossing them to a *pet<sup>+</sup> (rho<sup>0</sup>)* tester strain. The resulting diploid strains, plated above and used in all experiments described here, are referred to by the original haploid names for simplicity. The spontaneous revertants were isolated from the diploid mutant strains.

**Fig. 2** Mitochondrial translation products of wild type, *oxi-1* mutant and revertant strains. Cells of strains M13-249 (a), wild type (b), M5701 (c), revertant of M5701 (d), M5631 (e) and revertant of M5631 (f) were labelled with  $^{35}\text{S}\text{O}_4^{2-}$  in the presence of cycloheximide in medium containing 2% galactose as described<sup>27</sup>. The mutant cultures contained revertants at frequencies  $<5 \times 10^{-5}$ . Mitochondria were isolated<sup>28</sup> and subjected to electrophoresis in a gel containing 15% polyacrylamide in the presence of SDS. The gel was dried and autoradiographed. The arrow indicates the position of cytochrome oxidase subunit II.

and subjected to SDS-gel electrophoresis. The mitochondrial translation products were visualized by autoradiography. The non-leaky mutant M13-249 failed to synthesize detectable amounts of cytochrome oxidase subunit II (Fig. 2a) as has been previously reported<sup>9</sup>. The leaky mutants M5701 (Fig. 2c) and M5631 (Fig. 2e), on the other hand, both produced small amounts of a polypeptide with the same electrophoretic mobility as wild-type subunit II (Fig. 2b). (A second polypeptide, moving slightly faster than subunit II, is also evident in these mutants and faintly visible in the wild type. As shown below, this protein is apparently not related to subunit II.) By densitometric scanning of autoradiograms, the amount of subunit II labelled in the mutants was estimated to be roughly 5% of that found in wild type at 30 °C. When cells were grown and labelled at 20 °C, the labelling of subunit II in the mutants was further decreased relative to wild type but was still detectable (not shown). Whether this further decrease accounts for the tight negative growth phenotype of the mutants at 20 °C is unknown. Labelling of subunit II was normal in the spontaneous revertants of both mutants (Fig. 2d, f).

To confirm that the faint bands observed in Fig. 2 indeed represented the cytochrome oxidase subunit, the labelled mitochondrial extracts were subjected to antibody precipitation with an anti-subunit II serum. SDS-gel analysis of the precipitates confirmed that the mutants M5701 and M5631 (Fig. 3c, e) had produced small amounts of the full-sized protein (molecular weight (MW) 27,000), whereas the non-leaky mutant (Fig. 3a) had produced none. In addition, a shorter polypeptide fragment

(arrows in Fig. 3). These fragments can also be seen as faint bands in the total mitochondrial translation products<sup>10</sup> (Fig. 2). In the case of the non-leaky frameshift mutant M13-249, the shorter fragment (MW 17,000) is known to result from termination at an out-of-frame nonsense codon downstream from the mutation<sup>3</sup>. As will be shown below, the fragments observed in the mutants M5701 and M5631 (MWs 9,600 and 12,500, respectively) are produced in a similar manner. One might therefore expect the labelling intensity of the mutant fragments to approximate that of subunit II in the wild type, correcting for the lower MW. However, the fragments are much less intense (Figs 2, 3). Possibly they are less stable than the wild type protein. A further caution regarding the quantitative interpretation of these autoradiograms is that the intensity of labelling in the presence of cycloheximide may not accurately reflect the relative level of proteins in growing yeast cells.

Several minor species are also present in the antibody precipitates of the wild type and revertants. In addition to small amounts of subunits I and III of cytochrome oxidase, at least four lower molecular weight polypeptides can be seen (Fig. 3) which seem to be related to subunit II insofar as they are very strongly reduced in the mutants. The origin of these smaller polypeptides is unknown.

Taken together, the above findings suggest that the leaky growth phenotype of mutants M5701 and M5631 is due to the

**Fig. 3** Antibody precipitation of cytochrome oxidase subunit II and related polypeptides. The radioactively labelled mitochondrial translation products from the experiment of Fig. 2 were solubilized in SDS and subjected to immune precipitation<sup>29</sup> with a rabbit antiserum prepared against purified cytochrome oxidase subunit II (obtained from G. Schatz). The antibody precipitates were dissolved in SDS and electrophoresed on a 15% polyacrylamide gel which was dried and autoradiographed. As in Fig. 2 the labelled proteins were from M13-249 (a), wild type (b), M5701 (c), revertant of M5701 (d), M5631 (e) and revertant of M5631 (f). The position of subunit II in the gel is indicated, and small arrows in the autoradiogram indicate 'fragment' polypeptides specifically precipitated from the mutant extracts.

**Fig. 4** Position of the mutations within the gene sequence. The horizontal line represents the sequence coding for cytochrome oxidase subunit II (753 base pairs), translated from left to right. The *PvuII* site (at position -147 in the sequence of ref. 3) utilized in the experiments of Fig. 5 is indicated by P, and the direction of sequencing by the arrow. The run of T residues affected by the mutations starts five base pairs upstream from the *PvuII* cut.

presence of reduced amounts of a functional form of cytochrome oxidase subunit II, and that this deficiency is caused by frequent premature polypeptide chain termination during translation of the protein.

### Identification of frameshifts in the DNA sequence

To establish the nature of the mutations in strains M5701 and M5631, a 2,400-base pair *HpaII* restriction fragment that carries the entire *oxi-1* locus<sup>3,11</sup> was isolated from the total mitochondrial DNA of each strain for sequence analysis. The positions of the mutations were estimated to be about one-third of the way into the gene based on the apparent MWs of the subunit II fragments observed. A *PvuII* cleavage site lies in this region<sup>3</sup> (Fig. 4) and was utilized for end labelling and sequence determination by chemical degradation<sup>12</sup>. Alterations in the DNA sequence of both mutants were found in a run of five T residues present in the wild type sequence immediately upstream from the *PvuII* site (Fig. 5a). In the mutant M5701, this run is shortened to four T residues by a single base-pair deletion (Fig.

5b) whereas in the mutant M5631 the run is lengthened to six T residues by a single base-pair insertion (Fig. 5d). Spontaneous revertants of each strain (Fig. 5c, e) were restored to wild-type sequence, indicating that no undetected second site mutations are present.

The predicted consequences of the -1 and +1 frameshifts for translation are shown in Fig. 6 based on the known sequence of the wild type gene<sup>3</sup>. Shortening of the T run (underlined) to four bases should lead to a TAA stop codon after the addition of two amino acids out of frame. Lengthening the T run to six should result in the addition of 29 amino acids out of frame, yielding a significantly longer fragment polypeptide. These predictions are in excellent agreement with the apparent MWs of the subunit II fragments detected in the experiment of Fig. 3.

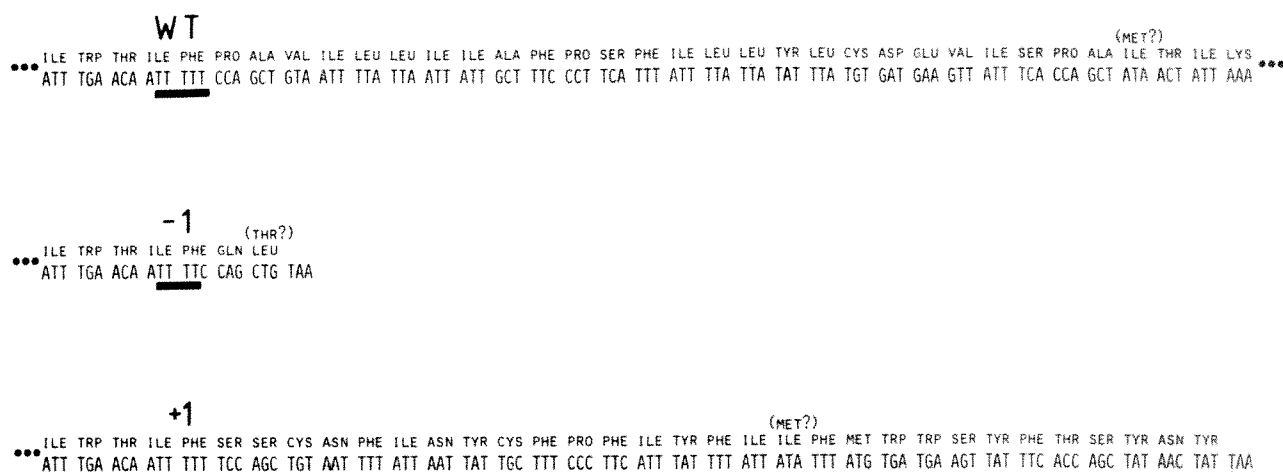

### Restoration of reading frame

The experiments described here show that despite the presence of a +1 or -1 frameshift mutation at a particular site in the yeast mitochondrial gene coding cytochrome oxidase subunit II, a significant amount of the full-sized gene product is formed. Thus, during the expression of these mutant genes, compensating errors must be made at or near the site of the mutations to restore translation to the proper reading frame. Although it is difficult to quantify accurately the frequency of reading frame restoration (see above), it seems to be roughly 5%. Leakiness of frameshift mutations in the  $\beta$ -galactosidase gene of *Escherichia coli* has been previously reported<sup>13</sup>. However, the levels there were 2 to 4 orders of magnitude lower than those described here.

The site affected by these *oxi-1* mutations is a run of five T residues. Whatever the mechanism that restores the reading frame, it is clearly site specific to some extent because at least one other frameshift mutation in this gene (a -1 mutation in a non-monotonous sequence) is not leaky (Figs 1-3 and refs 3, 9). Indeed, it seems likely that the compensating errors are made at the affected T run: eight of the 10 amino acid residues surrounding the site are identical in the yeast and bovine proteins<sup>3,14</sup>, indicating that they have functional significance. If

**Fig. 5** Identification of a single base-pair deletion and a single base-pair insertion in the *oxi-1* locus of the leaky mutants M5701 and M5631, respectively. Mitochondrial DNA fragments labelled on the 3' end<sup>3</sup> at the *PvuII* site indicated in Fig. 4, were isolated from wild type (a), M5701 (b), spontaneous revertant of M5701 (c), M5631 (d) and spontaneous revertant of M5631 (e), and subjected to chemical degradation sequencing reactions<sup>12</sup>. Autoradiograms of the products after separation on 20% polyacrylamide gels are shown. The arrow heads next to the panels point to the T residues in the affected run. As indicated, M5701 is a -1 frameshift and M5631 is a +1 frameshift.

**Fig. 6** Predicted translational consequences of the -1 and +1 frameshifts. A portion of the wild-type sequence (WT) (from ref. 3) including the site of the mutations (underlined) is shown. Out-of-frame translation beyond the mutations is shown up to the first termination codon encountered for the -1 and +1 mutations. Possible alternative codon assignments<sup>2,4</sup> are indicated in parentheses.

compensating errors were made anywhere other than at the site of the mutations, at least some of this conserved amino acid sequence would be garbled.

It seems likely that a single mechanism underlies the reading frame restoration in both the +1 and -1 frameshift mutants. One scheme which immediately suggests itself would suppose that during translation of this monotonous sequence, a slippage of the ribosome and/or peptidyl-tRNA relative to the mRNA can occur in both directions. If, for example during translation in the -1 mutant, the ribosome were to slip back one nucleotide after peptidyl-transfer to the tRNA<sup>Phe</sup>, the next codon exposed to the incoming aminoacyl-tRNA (CCA) would be in the wild type reading frame. Similarly, forward slippage would restore the wild type frame in the +1 mutant. In both cases, the peptidyl-tRNA<sup>Phe</sup> would still be sitting on a Phe codon after the slip. A formally equivalent possibility would be that the ribosome occasionally translocates two or four nucleotides at this site. Similar but less frequent events presumably lead to the observed leakiness of +1 and -1 frameshift mutations in *E. coli*<sup>13,15,16</sup>.

Several lines of evidence indicate that tRNA structures have an important role in maintaining reading frame during translation. First, mutated tRNAs are capable of suppressing +1 frameshift mutations both in bacteria<sup>17-19</sup> and in the nucleocytoplasmic genetic system of yeast<sup>20</sup>. The frameshift-suppressor tRNAs have generally been supposed to 'read' a 4-nucleotide codon, although it now seems that the actual mechanism may involve the induction of ribosomal frameshifting by the altered conformation of these mutant tRNAs<sup>16,21</sup>. Furthermore, some normal tRNAs can also promote ribosomal frameshifting in both directions when added in excess to an *in vitro* translation system<sup>22</sup>. It is therefore very interesting that the wild type yeast mitochondrial tRNA<sup>Phe</sup>, which is involved in translation at the site of the leaky frameshift mutations, has a unique structure:

the TΨC-stem contains an extra nucleotide which cannot be base-paired<sup>1,23</sup>. This extra unpaired nucleotide surely affects the conformation of the tRNA, and it is tempting to speculate that the novel structure may either induce ribosomal frameshifting or promote the slippage of the peptidyl-tRNA<sup>Phe</sup> relative to the mRNA. A precedent for this kind of hypothesis is provided by the case of the *E. coli* tRNA<sup>Trp</sup><sub>UGA</sub> suppressor, in which a sequence alteration in the D-stem confers the ability to read UGA codons on an otherwise normal tRNA<sup>Trp</sup> (ref. 24).

A somewhat different, and perhaps less likely model to explain the frequent frameshifting would suppose that the mitochondrial RNA polymerase occasionally 'slips' while transcribing a run of A residues, thus producing a small amount of wild-type mRNA from a gene carrying a frameshift. This hypothesis can probably now be tested using a heterologous translation system<sup>25</sup> programmed with mitochondrial mRNA from the leaky frameshift mutants.

Whatever the mechanism, it is clear from the results presented here that an extraordinarily high rate of reading frame errors occurs at specific points during the expression of at least some yeast mitochondrial genes. This obviously predicts that small amounts of prematurely terminated (and possibly extended) polypeptides should be synthesized by wild-type mitochondria as a result. Although we have not explicitly tested this prediction, it is not contrary to experience, in that many faint bands can always be detected in cycloheximide labelling experiments like that of Fig. 2 (see also Fig. 3). Such frameshifted proteins might be a burden tolerated by the cell. However, it is also possible that frameshifting at specific sites leads to the synthesis of physiologically important products.

We thank J. Wey and S. Stämpfli for technical assistance and R. Hall for a critical reading of the manuscript. B.W.-B. was supported in part by stipends from EMBO and Euratom. This work was supported by a grant from the Swiss NSF.

## The Jodrell Bank radio-linked interferometer network

J. G. Davies, B. Anderson & I. Morison

University of Manchester Nuffield Radio Astronomy Laboratories,  
Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

The Multi Telescope Radio Linked Interferometer (MTRLI) has just been brought into operation at Jodrell Bank and here we introduce the instrument, describe its capabilities, and present some of the first maps to be made with it. MTRLI produces high quality maps of radio sources with resolutions varying from  $\sim 1$  arcs to  $\sim 0.02$  arcs depending on the frequency of operation. The obvious astronomical use of the instrument is for the mapping of powerful extragalactic radio sources to investigate the physical processes within them, but it will also have the capability to map galactic line as well as galactic continuum sources. The maps presented here were made at 408 MHz and are all of extragalactic sources. They illustrate the ability of MTRLI to map at low frequencies the steep spectrum emission which tends to be overlooked with existing synthesis instruments which have to work at much higher frequencies to obtain the same resolution.

The MTRLI which has been under construction since 1975 and is an extension of the long baseline interferometers first operated at Jodrell Bank<sup>1</sup> in 1954 over a baseline of 0.91 km (480 wavelengths). Subsequently the baselines were suc-

cessively increased by using radio links<sup>2</sup> to 127 km (2 million wavelengths) by 1967 (ref. 3). The present MTRLI concept was proposed in 1974 by Palmer as a further improvement and extension of these two telescope interferometer systems. The MTRLI uses one of the two large telescopes at Jodrell Bank, (the MK IA 76-m telescope or the MK II 25 $\times$ 37-m telescope) and the existing outstations at Defford and Wardle, together with three new 25-m telescopes sited at Knockin Darnhall and Tabley which are of the E-Systems design as used in the VLA. The first phase of the instrument using four telescopes is now working; the second phase in which the Darnhall and Tabley telescopes are added to the array will be complete by the end of 1980. When all telescopes are in use, data can be obtained from 15 baselines simultaneously ranging from 133 to 6 km in length. The system will be operated at a variety of wavelengths ranging from 73 to 1.35 cm, although at the higher frequencies not all telescopes are usable. Figure 1 indicates the position of the telescopes and the orientation of the baselines. The three new telescopes were sited to provide reasonably uniform coverage of the spatial frequency components of the sky brightness distribution. This is shown in Fig. 2 for declinations 10° and 50° north for the 15 baselines of the array. Because of the large N-S component in many of the baselines the resolution in the N-S direction remains comparable to that in the E-W direction even at low declinations.

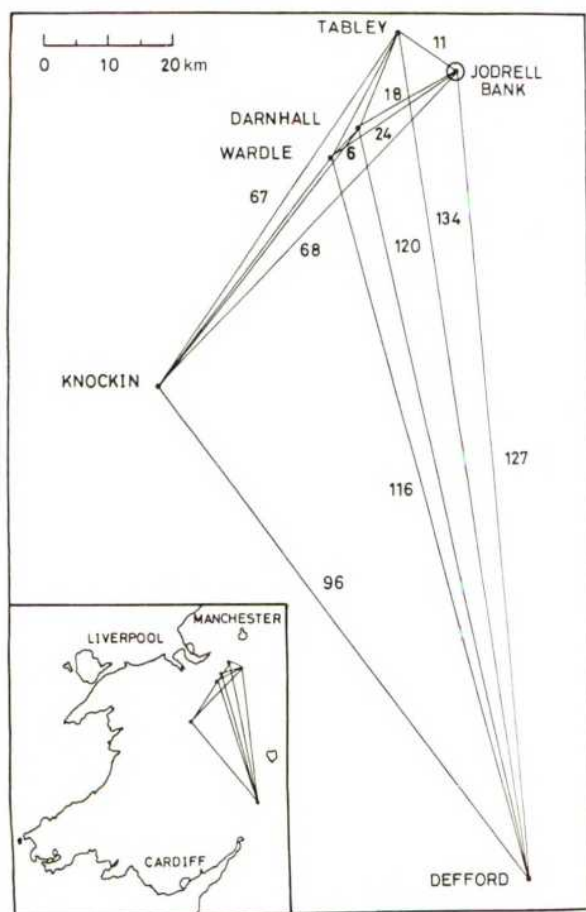

Fig. 1 The relative positions of the MTRLI telescopes with the baseline lengths given in kilometres.

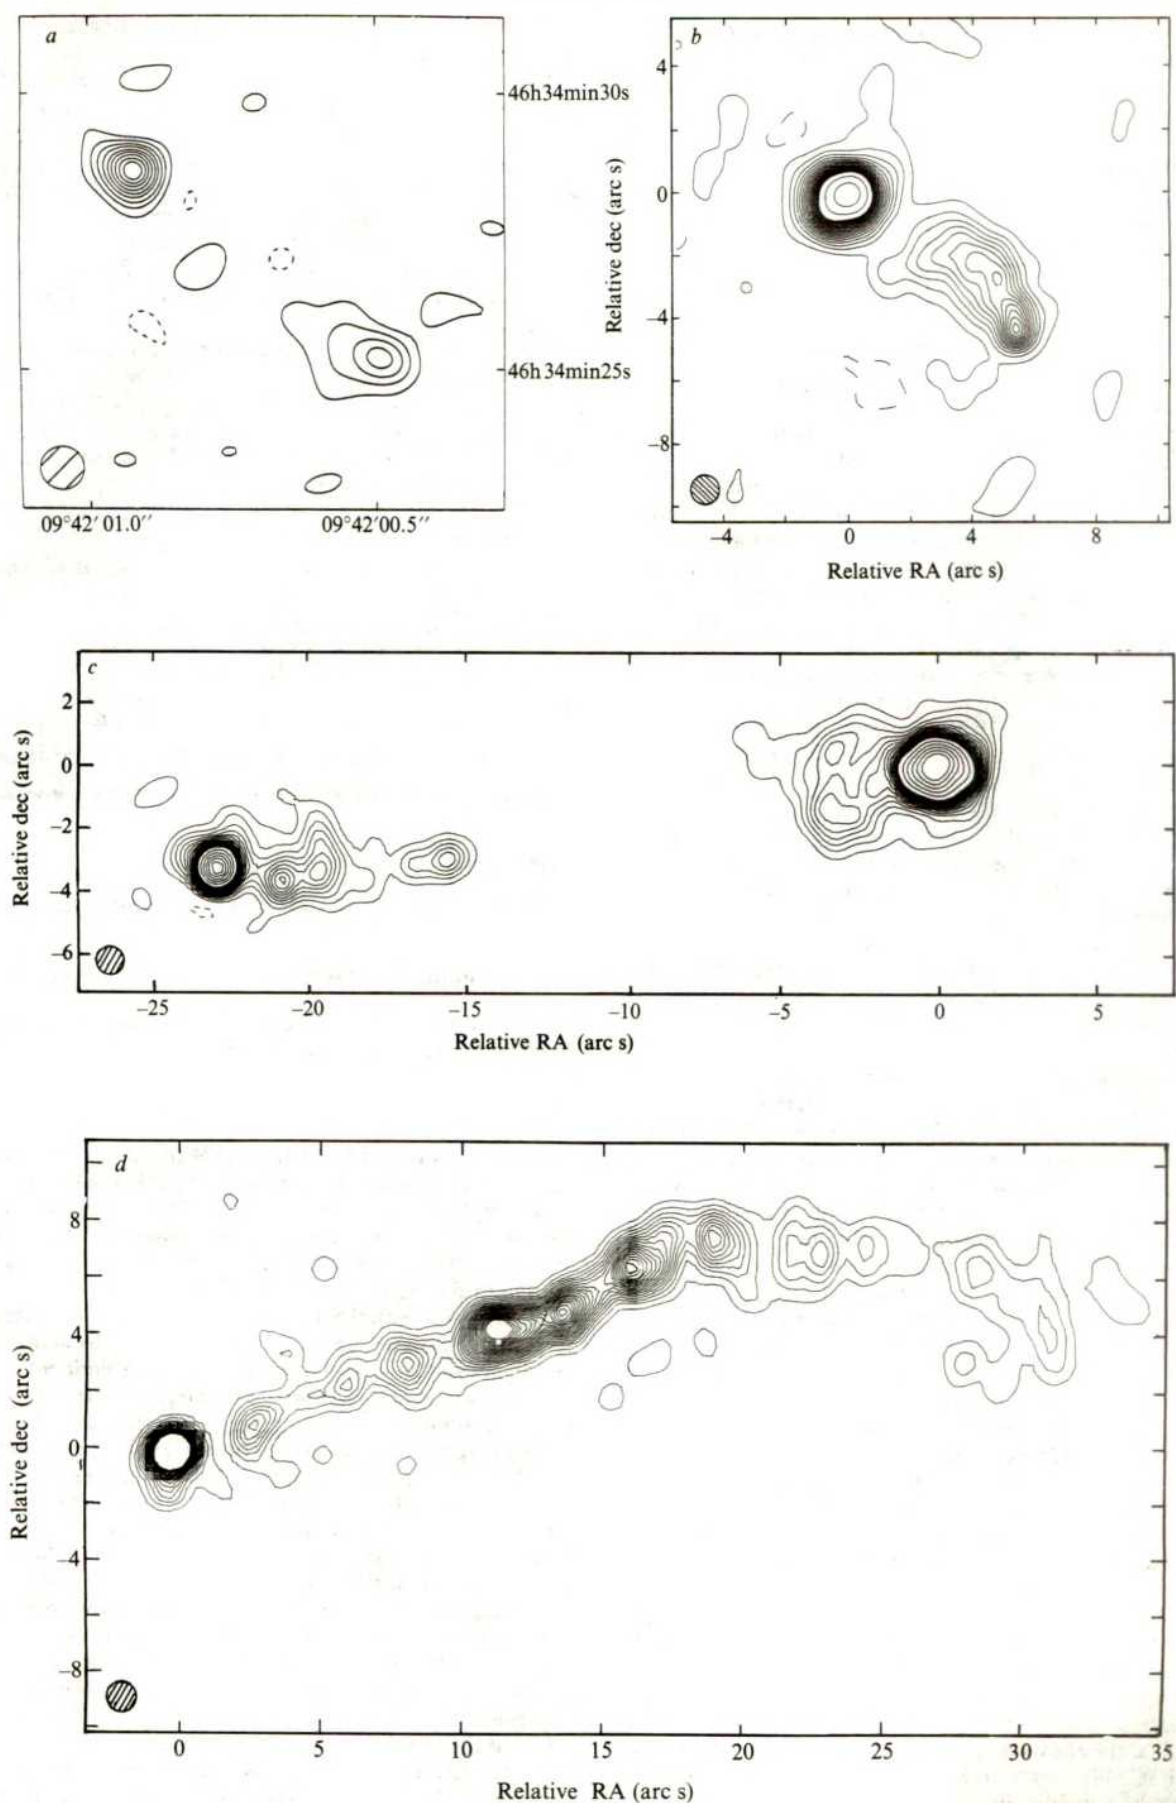

Fig. 2 The projected spacings of the MTRLI baselines for sources of declination: a, 10°; b, 50°. One division represents 100 km.

Each outstation telescope has an on-line computer to provide local control of the telescope and receiver or allow remote operation by land line from Jodrell Bank. Standard microwave links with a bandwidth of 10 MHz carry the radio signals from the outstations to Jodrell Bank, using two repeater stations in the case of Defford and Knockin, and direct for the nearer telescopes. Local oscillators at all sites are phase locked using a single frequency near 1,500 MHz. Pulses at this frequency are transmitted from Jodrell Bank to the outstations over the same paths as are used for the microwave links, locking high quality crystal oscillators at each repeater site and telescope. Pulses are then returned over the same paths and the received phase compared with that transmitted. In this way changes in the electrical path lengths are continuously measured with an accuracy of about 1 mm in 150 km, and corrections made to the phase of the received signals.

At Jodrell Bank the signals from each telescope are passed through phase rotators to remove the effects of the Earth's rotation, an analogue delay continuously variable between 0 and 75 ns and a digital delay of up to 1 ms in 50-ns steps to compensate for the varying geometry of the telescope baselines. The signals are then taken in pairs and correlated in a set of

**Fig. 3** The MTRLI maps. *a*, 5C5.168 at 408 MHz; the contour interval is 2 mJy per beam area. *b*, 3C153 at 408 MHz; the contour levels are 1, 3, 5...33, 35, 50, 75% of peak brightness; *c*, 3C249.1 at 408 MHz; the contour levels are 2, 4, 6, 8...28, 30, 40, 50, 60, 70, 80% of peak brightness. *d*, Virgo A at 408 MHz; the contour levels are 2, 4, 6, 8...38, 40% of peak brightness. The half-power beamwidth of the circular gaussian restoring beam is shown in each case in the lower left-hand corner.

one-bit correlators. These are normally connected as 16 complex correlators each with 32 channels of delay. If two or more sources are to be observed simultaneously in one telescope beam, the differential delay for the longer baselines may exceed the  $32 \times 50$  ns available from one of these correlators. In this event the correlators can be connected together to provide fewer independent correlators with a larger number of delays. Integration over 1 s is performed within the correlators, and the data are then passed to a purpose designed computer where further integration, processing and storage takes place.

Sources are typically observed at all hour angles where the elevation remains above  $5^\circ$  and maps of the brightness distribution are produced by the CLEAN<sup>4</sup> technique to remove unwanted sidelobe responses of  $\sim 5\%$  caused by the incomplete spatial frequency coverage of the array.

The inherent phase stability of the interferometers and hence the map making capability of the system is fundamentally limited by the atmosphere above each telescope, with tropospheric effects being most important at high frequencies and ionospheric effects at low frequencies. These limitations may be overcome by determining the phase of the source being mapped relative to that of a nearby reference source. At low frequencies the source and a suitable reference can often be observed simultaneously within the telescope beam<sup>4</sup>, but at high frequencies it will be necessary to alternate between the source and reference on a time scale short compared with that of the fluctuations. Alternatively, with the sacrifice of positional information, one can produce maps which use the closure phase relationships<sup>6</sup> between different combinations of telescopes. Cornwell and Wilkinson<sup>7</sup> developed a mapping algorithm which corrects amplitude and phase errors arising at the separate telescopes in the array. This is exactly equivalent to using the closure amplitudes and phases as in the approach adopted by the standard 'hybrid' mapping algorithms of Readhead and Wilkinson<sup>8</sup> and Readhead *et al.*<sup>9</sup>. The new algorithm is rather more general than these earlier ones and extensive tests on simulated data have shown that maps of complex sources made from typical MTRLI data are reliable down to  $\sim 1\%$  of the peak brightness.

Observations of about 30 extragalactic sources were made during January and February 1980 at 408 MHz with a four-telescope array comprising the MK IA and the Wardle, Knockin and Defford telescopes. The observations provide an extreme test of the mapping ability of the system in that there were only six baselines available and the data were obtained in severe ionospheric conditions near the time of maximum solar activity. A full astronomical discussion of most of the results will be given elsewhere but we present in Fig. 3 a few of the maps produced from the observations to illustrate the capabilities of the system. The map of 5C5.168 was produced by reference to a source elsewhere in the beam, the remaining maps were produced using the new hybrid mapping technique.

5C5.168 (Fig. 3a) is one of four 5C sources mapped simultaneously using 5C5.175 as a reference source. This is a double source of 6 arc s separation with a total flux of 70 mJy. The contour interval is limited by noise at 2 mJy per beam area. Because an accurate position measurement for the reference source is available, the positions of the components of 5C5.168 are determined to  $\sim 0.2$  arc s, but even with such accuracy the source remains unidentified on the Palomar Sky Survey down to 20th magnitude. The ability of MTRLI to map such weak sources means that we can investigate how the morphologies of radio sources depend on luminosity. This in turn is a prerequisite for the investigation of angular size evolution.

Figure 3b, and c shows maps of two high luminosity sources 3C153 and 3C249.1 respectively. The large dynamic range of the maps enables the details of the point features between the main peaks of emission to be seen clearly. Note that in both sources there is emission stretching from near the optical object out to just one of the lobes; in each case the second lobe appears completely isolated. Perhaps the emission is from the beam which is thought to transport energy from the nucleus to the

outer lobes, and then the asymmetry could be explained by relativistic beaming.

The map of Virgo A is included to illustrate how well MTRLI can map complicated sources with just four telescopes. That the details of the map are substantially correct is demonstrated by the coincidence of the radio and optical knots and by the good agreement found between the main features in the present map and that made with the VLA at 5 GHz (ref. 10).

MTRLI observations at 1,666 MHz of all the present sources are planned and detailed astrophysical discussion of the combined 408- and 1,666-MHz observations will be given elsewhere.

The construction of the MTRLI has involved major effort by many members of staff at Jodrell Bank, but we particularly thank J. A. Battilana, M. Bentley, A. Brown, D. C. Brown, R. D. Davies, R. J. Davis, M. Doggett, J. S. Haggis, J. Hopkins, R. G. Noble, H. P. Palmer, L. Pointon, R. S. Pritchard, D. Stannard and P. Thomasson.

## Rotationally symmetric structure in two extragalactic radio sources

C. J. Lonsdale & I. Morison

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

Many extragalactic radio sources exhibit radio structures with some degree of rotational symmetry<sup>1,2</sup>, which in extreme cases (for example, 3C315 (ref. 3) and NGC326 (ref. 4)) suggests precession of the source axis, such as might result if a relativistic beam of particles<sup>5,6</sup> or stream of plasmoids<sup>7</sup> were to change its orientation during the source lifetime<sup>1</sup>. In such circumstances we might expect radiative and other energy losses to steepen the spectrum of the older regions of emission<sup>8</sup> away from the current sites of activity, and so make them more prominent on low-frequency maps of the source structure. The new multi-telescope radio-linked interferometer (MTRLI)<sup>9</sup> at Jodrell Bank was used during January and February 1980 at a frequency of 408 MHz to map the extragalactic radio sources 3C196 and 3C305 with a resolution of  $\sim 1$  arc s. We show here that both the markedly symmetric structures observed and the spectral index distributions inferred from comparison with previously published 5-GHz maps<sup>10</sup> provide evidence for the source axes having rotated during the lifetime of the emitting regions.

The sources were observed using four telescopes of the MTRLI, with projected interferometer spacings ranging between  $\sim 15$  and 127 km. Over such distances the effects of ionospheric disturbances at the low observing frequency are large and the absolute phase information was not recoverable. Consequently, the closure-phase hybrid mapping technique described by Readhead and Wilkinson<sup>11</sup> was used, though with a significantly improved algorithm<sup>12</sup>. The absolute positions of the components on these maps, lost in the hybrid mapping technique, were inferred from a comparison with the Cambridge 5-GHz maps. The main characteristics of the two sources are given in Table 1.

**Table 1** Some relevant characteristics of 3C196 and 3C305

| Source                             | 3C196   | 3C305   |
|------------------------------------|---|---|
| Optical identification             | 18 m OVV quasar   | 13.5 mag Sa pec galaxy <sup>14</sup>                              |
| Redshift                           | 0.871   | 0.0416  |
| Radio structure at 5 GHz (ref. 10) | 2 main components. Third weaker component at 90° to source axis from N main component | 2 main components surrounded by an extended low-brightness region |
| Separation of 2 main components    | 5 arc s   | 3.4 arc s   |
| Projected linear size              | 43 kpc  | 3.8 kpc   |
| Overall radio spectrum             | Power law $\alpha = -0.81$  | Power law $\alpha = -0.86$  |
| Integrated radio luminosity        | $4.2 \times 10^{45}$ erg s <sup>-1</sup>  | $1.8 \times 10^{42}$ erg s <sup>-1</sup>                          |

\* Assuming  $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$  and  $q_0 = \frac{1}{2}$ .

The MTRLI map of the high luminosity radio source 3C196, a quasar, is based on 16-h observation and is shown in Fig. 1. The projected linear size of the source is  $\sim 50$  kpc. Components A and B are assumed to correspond to the main components on the Cambridge 5-GHz map. Component B' is identified as the third component on the Cambridge map, and is revealed to be an extended region of emission with a steep spectrum. Component A', which was not detected at 5 GHz and therefore has a steep spectrum, is a much weaker extended region, with a slight plateau at some distance from component A. A line drawn from this plateau to the peak of component B' passes through the position of the optical object. The physical properties of the components are listed in Table 2. Note that component A is significantly more extended than component B. The spectral indices of the components have been obtained by comparison with other published<sup>10,13</sup> data. Note that in addition to the spectral differences between the compact components A and B in 3C196, the extended components A' and B' display markedly different morphologies and luminosities which may indicate time-dependent asymmetry in the power supply mechanism. Planned observations with higher resolution should enable this aspect of the source properties to be investigated.

The source 3C305, which is highly unusual for a 3C source in being identified with a 13.5 mag Sa peculiar galaxy<sup>14</sup> of dimensions  $\sim 20 \times 30$  kpc, is a relatively low-luminosity radio source, and the two compact components are separated by a projected linear distance of only 3.8 kpc. A strong absorption lane crosses the body of the galaxy at an oblique angle, and there is a region of O II [ $\lambda 3,727$ ] emission centred in a position 3 arc s to the NE of the nucleus<sup>14</sup>. The MTRLI map of 3C305, based on 24-h data, is shown in Fig. 2. The rotational symmetry displayed on this map is striking. The extent of the low brightness regions A' and B' may be somewhat greater than is shown because only 85% of the total flux has been accounted for in the map. The spectral indices of the two main components and extended regions are given in Table 2. The apparent symmetry in this source is greater than in 3C196 because the intensity ratios A:A' and B:B' are similar. Component C is a possible candidate for a compact source associated with the optical nucleus of the galaxy. If this is the case, the region of O II [ $\lambda 3,727$ ] emission lies close to the strong component B, but the uncertainty in the optical position prevents positive association.

In both 3C196 and 3C305, the rotational symmetry and the steep spectral indices (normally associated with the ageing of synchrotron electrons) of the extended components suggest that the axes of the radio sources have changed their orientation relative to the medium in which the sources are embedded. Hitherto, examples of such symmetry have been confined to

sources of large linear extent and relatively low luminosity. Thus these sources are very unusual not only for the degree of symmetry displayed, but also because they are small in linear size, and because 3C196 is an exceptionally powerful source.

Clearly, it is important to know the time scale on which such a rotation of the axis occurs. However, the determination of such a time scale is hampered by our ignorance of the physical conditions prevailing in and around the radio source components, and our lack of understanding of the mechanisms governing source evolution.

For component B' in 3C196 the spectral information in Table 2 allows us to make a rough estimate of the cut-off frequency  $\nu_c$ , above which we expect the spectrum to steepen markedly due to the energy losses of the radiating electrons<sup>8</sup>. If we assume that these energy losses are purely radiative, we can deduce how long the component has been radiating without any fresh input of high-energy electrons. This time is  $\sim 2 \times 10^5$  yr, which is thus the corresponding time scale  $t$  for the rotation of the source axis. The accuracy of this estimate depends critically on the validity of neglecting both adiabatic expansion losses and particle reacceleration gains.

If we accept that in 3C196 the energy supply from the quasar was once directed at component B' and is now directed at component B, it is reasonable to assume that in the past, component B' was a similar distance from the QSO as component B is now. Because component B' is now only slightly more distant from the QSO than component B, it cannot have moved by more than  $\sim 10$  kpc in the time taken for the source axis to swing through 65°. By assuming (1) that component B' is confined by ram pressure and (2) that the average internal energy density of the component during this period was no lower than it is now, we can deduce the minimum velocity of the component through the intergalactic medium which is required to confine it. Assuming an upper limit for the density of the intergalactic medium<sup>15</sup> of  $\sim 10^{-27} \text{ g cm}^{-3}$ , we find that a velocity of  $\geq 0.03c$  is required to confine the component by ram pressure, and so the time scale  $t$  for the source axis rotation is  $t \leq 10^6$  yr.

The rate of advance of a component through the surrounding medium deduced from the internal energy density of that component may enable us to set a lower limit on the time scale for the source axis rotation at present. From the appearance of component B' in 3C305 and the apparent gap between

\* Approximate values only, see text.

The spectral indices are defined in the sense  $S \propto \nu^\alpha$ . The sizes given are the dimensions of an equivalent gaussian. The minimum energy was calculated assuming that there are no relativistic protons, and assuming cylindrical component geometry. Equipartition of energy between relativistic particles and magnetic field was also assumed. The spectral age  $T_{\text{sp}}$  was calculated by assuming that spectral steepening is caused only by radiative energy losses, and by estimating the cut off frequency  $\nu_c$  from the spectral data. Assuming  $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$  and  $q_0 = \frac{1}{2}$ .

components B' and B in 3C196, it is reasonable to suppose that the beam may have been switching on and off. If the source axis rotated through a significant angle whilst the beam was switched off, it would then have to re-excavate a channel through the surrounding medium, and this would take place at the above mentioned rate. Clearly, during the time taken for this excavation, the axis cannot rotate by more than the angle subtended between two discrete emitting regions. Assuming for 3C196 a typical intracluster medium density of  $\sim 5 \times 10^{-28} \text{ g cm}^{-3}$ , and for 3C305 (because it is embedded in the galaxy) a typical interstellar medium density of  $\sim 10^{-25} \text{ g cm}^{-3}$ , we find that the present rotation time scale for 3C196 is  $t \geq 10^6 \text{ yr}$  and for 3C305 is  $t \geq 5 \times 10^6 \text{ yr}$ . If the assumptions inherent in these values are valid, this may indicate that the rotation rate in 3C196 has slowed down.

**Fig. 2** The MTRLI map of 3C305 at 408 MHz. The contour levels are 1, 2, 4, 6, ..., 24, 30, 40, 50, 60, 70, 80, 90% of peak brightness. The HPBW of the circular gaussian beam is shown in the bottom left corner. +, The position of the nucleus of the galaxy.

The time scales we find for the rotation in these sources are very much shorter than those typically deduced for the larger sources. For example, Ekers *et al.*<sup>4</sup> arrive at a value of  $\sim 2 \times 10^8 \text{ yr}$  for NGC326, and this difference may indicate that the size of a source such as 3C196 is limited by the rapid rotation. Alternatively, we may be seeing the results of two completely

different mechanisms for producing the rotational symmetry. Ekers *et al.*<sup>4</sup> mention that the precession of gaseous disk in the galaxy would probably lead to a long time scale. We will briefly consider an alternative mechanism that seems capable of producing a more rapid rotation.

Rees<sup>16</sup> has discussed the possibility that the Bardeen-Peterson<sup>17</sup> effect couples the radio axis to the rotation axis of a massive black hole at the centre of a galaxy, thereby stabilizing the beam against 'jitter' resulting from uneven accretion. If the accreted mass had an angular momentum direction different to that of the black hole, the radio source axis would swing appreciably on a time scale equal to the time it would take for the black hole to double its mass. If the postulated black hole in 3C196 is radiating at its Eddington luminosity, (see, for example, ref. 18) it must have a mass of at least  $5 \times 10^7 M_\odot$  deduced from the radio power alone, and so to produce a rotation of the source axis on a time scale of  $\sim 10^6 \text{ yr}$ , the accretion rate would have to be at least  $50 M_\odot \text{ yr}^{-1}$ . The implied efficiency of conversion of accreted rest mass into relativistic particle energy leading to radio emission is  $\sim 0.2\%$ . The corresponding efficiency for 3C305 is  $\sim 1\%$  assuming a rotation time scale of  $5 \times 10^6 \text{ yr}$ . If the efficiency of conversion of accreted rest mass into energy was as much as  $\sim 30\%$ <sup>19</sup>, the rotation time scale would be at least  $\sim 10^8 \text{ yr}$ , and the low efficiencies deduced here might create difficulties if 3C196, in particular, was found to be a strong X-ray or IR source.

In the case of 3C305, an alternative origin of the rotational symmetry is possible. The radio source is embedded in the galaxy, and if the axis of this source is not aligned with the rotation axis of the galaxy, then we might expect the galactic rotation to sweep energetic particles away from the compact hotspots in a rotationally symmetric fashion, thus producing the observed morphology. Sandage<sup>14</sup> deduces a rotation period of  $6.8 \times 10^7 \text{ yr}$  for the galaxy corresponding to a time scale of  $\sim 2 \times 10^7 \text{ yr}$  for the degree of rotation observed here, and thus does not conflict with the lower limit of  $\sim 5 \times 10^6 \text{ yr}$  deduced earlier.

The present observations strongly suggest that, in 3C196 and 3C305, the orientation of the source axis has rotated through a large angle over the source lifetime. Not only does the fact of source rotation place constraints on the source mechanism itself but its result is to separate spatially the radio emission generated at different stages in the source evolution. Future observations of such sources may thus provide valuable insights into the nature of radio sources in general.

We thank Drs D. Stannard and I.W.A. Browne for helpful discussions and comments. C.J.L. acknowledges an SRC research studentship.

## MTRLI observations of the double QSO at 408 MHz

R. G. Noble & D. Walsh

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

The suggestion<sup>1</sup> that the twin QSOs 0957 + 561 A, B, which are separated by  $\sim 6$  arc s and have emission redshifts 1.41, are images of a single QSO formed by a gravitational lens now seems to be generally accepted. This is a result of a wide range of data including optical spectroscopy<sup>2,3</sup> and, more particularly, direct imaging by CCD camera<sup>4</sup> and image-intensified photography (A. Stockton, personal communication) which reveal a galaxy, G1, with  $m_r \sim 18.5$  within 1 arc s of the QSO B. G1 can account for the splitting of the images<sup>4</sup>. It is the brightest member of a cluster<sup>4</sup>, has a redshift  $0.375 \pm 0.005$  (ref. 3) and IR observations confirm that it is a giant elliptical<sup>5,6</sup>. The flux density ratio of the two QSO components is nearly constant,  $B/A \approx 0.75$ , from  $\sim 3,000$  Å (ref. 7) to decimetre wavelengths<sup>8,9</sup>, as expected for gravitational imaging. The first radio maps<sup>10,11</sup> showed a complex structure and their initial interpretation was ambiguous, but there now seems to be agreement on the overall interpretation<sup>4,11,12</sup> in terms of gravitational imaging. Early observations at 408 MHz (ref. 10) suggested the flux density ratio of the two QSO components may differ significantly from that at shorter wavelengths, which would cast doubt on the gravitational lens interpretation. Recent observations at 5 GHz (ref. 13) indicate a point source 1 arc s from QSO B, coinciding closely with the position of G1. We present here a 408-MHz map which provides spectral information on all components of the radio source, removes the doubt raised by the earlier 408 MHz observations and sheds light on the nature of the source coincident with G1.

0957+561 was observed at 408 MHz for 24 h on 8–9 January 1980 with the Jodrell Bank multi-telescope radio-linked interferometer (MTRLI)<sup>14</sup> using four stations with six simultaneous independent baselines up to 127 km. Data were reduced by a CLEAN technique using closure phase and amplitude relations<sup>15</sup>, and restored with a synthesized beam of circular-gaussian shape with FWHM of 1.1 arc s. Using phase-closure relations means a loss of absolute positional information. Amplitude-closure relations were used to adjust gains of individual telescopes by amounts which in practice never exceeded 5%, and the resulting uncertainty contributed to the final flux scale is  $\leq 2\%$ . The flux scale was derived by reference to the compact source 3C119 which was assumed to have flux density 16 Jy. The peak of the resulting hybrid map (Fig. 1) is  $\sim 200$  times the r.m.s. noise.

The 408-MHz map shows the general features of the map made with higher resolution ( $0.66 \times 0.41$  arc s FWHM) at 5 GHz (ref. 13). In Fig. 1 the component associated with QSO A is unresolved. Component B shows extension in a direction roughly that of G1, presumably due to the point source detected

at 5 GHz. The emission north-following A shows similar structure to that at 5 GHz; it has a steeper spectrum than A and accounts for more than two-thirds of the flux of the whole source. The emission south-preceding A is extended in a similar direction to that seen at 5 GHz and has a spectrum similar to that of the north-following emission.

The structure of the emission in the neighbourhood of component B was investigated as follows. Profiles through the peak of B were examined in the direction of G1 and the perpendicular direction; lower-level contours than shown in Fig. 1, extending down to the noise limit, were used for this. (The best estimate of the position of G1, 0.99 arc s N and 0.19 arc s E of QSO B, comes from the photograph by Stockton (personal communication) in seeing of half arc s.) The sections in the E–W direction and southwards from the peak showed no deviation from the point-source response down to the noise level, whereas the northern skirt showed a systematic broadening. Accordingly we assume that the contribution of QSO B is that of a point source at the position of the peak on the map. (This is supported by the fact that the peaks of A and B on the map are separated by  $6.170 \pm 0.005$  arc s, in close agreement with the value of 6.175 arc s determined by VLBI<sup>8</sup>.) The flux density of B is 55 mJy. Subtraction of this point source leaves residual emission which is well represented by a point source of  $3.3 \pm 1.3$  mJy at a distance  $1.2 \pm 0.2$  arc s from B. This separation agrees well with the optical value quoted above for G1 and the 5 GHz value of 1.07 arc s (ref. 13).

**Fig. 1** Map of 0957 + 561 at 408 MHz. The zeros on both axes are arbitrary. The contour interval corresponds to a point source of 6 mJy; the zero contour is omitted, and negative contours are broken. The lowest contour is  $\sim 4\sigma$ . The half-power beam is indicated in the lower left corner.

The flux density of component A is 79 mJy. The ratio of flux densities,  $B/A$  is  $0.70 \pm 0.03$ , where the standard deviation quoted is derived from the estimated noise on the map. This value is within the range of published flux density ratios at shorter wavelengths from radio to UV. It extends by a factor of more than three the longest wavelength at which the ratio is accurately determined and replaces the anomalous value obtained previously<sup>10</sup> using single baselines of the present interferometer. There is evidence for variability of flux density at optical<sup>16</sup> and radio<sup>13</sup> wavelengths. Because sources generally vary less at 408 MHz than at higher frequencies, the new 408-MHz flux density ratio may be the most accurate value

**Fig. 2** Spectra of the compact components A (x) and B (o). 0.408 GHz, epoch January 1980 (this paper); 1.5 GHz, October 1980 (ref. 9); 1.67 GHz, February 1980 (ref. 17); 5.0 GHz (higher values), May 1979 (ref. 10); 5.0 GHz (lower values), February 1980 (ref. 13); 15 GHz, October 1979 (ref. 9).

available for the ratio inherent in the gravitational imaging process.

The radio spectra of A and B have now been determined over the range 0.408–15 GHz and are shown in Fig. 2, where the epochs of measurement are indicated. The values at 1,666 MHz are from VLBI observations using the European Network<sup>17</sup> and supersede those published previously<sup>8</sup>. The disagreement between the two values at 5 GHz is unlikely to be due to variation as the values determined in May 1979 with the Cambridge 5-km telescope<sup>10</sup> are considerably higher than the values determined with the VLA at three epochs<sup>11–13</sup> June and October 1979 and February 1980; one or both measurements are likely to have systematic errors. The spectra show marked curvature with a high-frequency fall-off, although the extent of this is strongly dependent on the 15-GHz values<sup>9</sup> which are only preliminary.

The weak component coincident with G1 may be emission from G1 itself or, more intriguingly, a third image of the QSO (or a combination of the two). Attention was drawn to the possibility of multiple imaging in the first published maps<sup>10</sup> and more thorough calculations<sup>4</sup> show a wide range of imaging geometries is possible, including ones giving rise to a third image close to the centre of G1. If the radio component is in fact a third image, its spectrum should be similar to that of A and B. We find the flux density ratio of B to this component is  $16 \pm 7$  at 408 MHz whereas the value at 5 GHz (ref. 13) is  $12.7 \pm 1.1$ . Thus it is possible that a third QSO image has been detected.

We thank our many colleagues at Jodrell Bank for the construction and operation of the MTRLI, and the development of data reduction techniques. We thank Dr Alan Stockton and Professor Bernard Burke for results before publication.

## Magnetic domain observations of nucleation processes in fine particles of intermediate titanomagnetite

S. Halgedahl & M. Fuller

Department of Geological Sciences, University of California, Santa Barbara, Santa Barbara, California 93106

The stable carriers of the palaeomagnetic record in rocks are commonly fine grains of magnetite or titanomagnetite ( $\text{Fe}_{3-x}\text{Ti}_x\text{O}_4$ ) between 1 and 15  $\mu\text{m}$  in diameter. The magnetic properties of these particles are therefore of interest to palaeomagnetists who must rely on them to preserve the Earth's magnetic field record over geological time. We report here domain observations of titanomagnetites in samples from Leg 49 of the Deep Sea Drilling Project. The results indicate that a major contributor to 'pseudosingle-domain' (PSD) saturation remanence is single domain remanence of particles larger than the classical single-domain threshold size which fail to nucleate domain walls in this magnetization state.

In contrast to larger, typically multidomain particles, the magnetic properties of titanomagnetites  $\leq 15 \mu\text{m}$  are strongly grain-size dependent. Within this range, the coercivity  $H_c$ , the ratio  $J_{rs}/J_s$  of saturation remanence to saturation magnetization, and the low-field ( $< 1 \text{ Oe}$ ) thermoremanent magnetization (TRM) acquired per unit volume of material increase roughly as  $1/L$  ( $L$  is grain size)<sup>1,2</sup> from nearly size-independent, multidomain values to their maxima at the single-domain boundary. The rapid rise of stability and remanence with decreasing grain size in particles still large enough to accommodate domain walls has led to their being referred to as 'pseudosingle-domain'<sup>3</sup>.

Stacey originally proposed that Barkhausen discreteness of domain wall position resulted in an intrinsic, undemagnetizable PSD moment<sup>3</sup>. It was later suggested<sup>4</sup> that PSD moments arise within surface closure domains, or within a fine structure in domain walls which terminate at the surface. Domain wall moments have also been considered as a source of PSD remanence in sub-micrometre size magnetite by Dunlop<sup>5</sup>, who referred to such moments as 'psarks'.

These PSD models are based on the assumption that particles larger than the classical single-domain threshold size contain domain walls, regardless of their magnetization state. The role of nucleation—the process by which domain walls are initially formed—has not been considered in PSD models. Yet Becker<sup>6,7</sup> has shown that the high coercivity of fine  $\text{Co}_5\text{Sm}$  particles is nucleation-controlled, and Banerjee<sup>8</sup> noted that nucleation sites

**Fig. 2** Small titanomagnetite particle undergoing hysteresis in an applied field parallel to the magnetization: *a*, state of saturation remanence after reducing saturating field of 1,500 Oe to zero. Arrow indicates sense of domain magnetization, which is parallel to grain surface. *b*, Nucleation of small reverse domain in a reverse field of -12 Oe. Domain wall is indicated by heavy black line. *c*,  $H = -30$  Oe. Note that this grain displays three-dimensional relief, and that the surface domain structure penetrates the grain volume. *d*,  $H = -40$  Oe, *e*,  $H = -48$  Oe.

may be the origin of high coercivity in fine-grained magnetite. The present domain observations strongly suggest that the nucleation process is important in determining the PSD properties of fine-grained titanomagnetite. These observations will be incorporated in a simple model which accounts for much of the grain-size dependence of  $J_{rs}/J_s$  in the PSD range.

Selected samples of oceanic basalt collected on Leg 49 of the DSDP were used for domain observations; their rock magnetic properties have been reported elsewhere<sup>9</sup>. The rocks chosen contain fresh titanomagnetite particles of composition  $x = 0.6$ . Specimens were first mechanically polished, and then ionically polished using the method of Soffel and Petersen<sup>10</sup> to obtain the strain-free surfaces necessary for domain observation. The walls were observed with the Bitter technique (Fig. 1).

A small ( $\approx 12 \mu\text{m}$ ) titanomagnetite particle undergoing hysteresis is shown in Fig. 2. The particle is initially saturated in a 1,500-Oe field. When the applied field is reduced to zero, the grain remains in the saturated state. On applying a 12-Oe reverse field, a small, reversely magnetized domain is nucleated. Further increase of the reverse field drives the wall towards the grain's interior, and magnetization reversal takes place by wall motion. The second half-cycle of hysteresis is identical to the first, except that the magnetization and field polarities are reversed.

Nucleation always occurs at the same location during each half-cycle, indicating that this grain utilizes only one nucleation site. As the polarity of the freshly nucleated reverse domain is always opposite to that of the saturating field, the grain has been truly saturated.

Similar behaviour has been observed in many particles of this size or smaller. In a population of 60 particles whose grain sizes are uniformly distributed between 5 and  $15 \mu\text{m}$ , 40% are observed to remain as single domains in saturation remanence, although one or more walls are subsequently nucleated in reverse fields. Another 40% of the grains contain two domains in saturation remanence, while the remainder contain three domains or more. It is also observed that grain size alone does not uniquely determine the saturation-remnant domain state, because particles of the same grain size exhibit a range of domain multiplicities.

These observations are consistent with the calculations of Brown<sup>11</sup>. For a wall to nucleate, the spins must initially overcome an energy barrier originating in the various anisotropy energies. Brown's nucleation condition requires that  $H_{ap} + H_d \geq 2K/J_s$ , where  $H_{ap}$  is the applied field,  $H_d$  is the demagnetizing field,  $2K/J_s$  is the anisotropy field, and where it is understood

that the sense of  $H_{ap} + H_d$  is opposite to that of  $J_s$ . Particles of certain materials will, therefore, theoretically never develop domain structure in saturation remanence ('Brown's paradox')<sup>12</sup>. However, there is considerable experimental evidence that nucleation occurs at surface imperfections at which there is either a strong, local demagnetizing field or an anomalously low anisotropy field<sup>6,13</sup>. When a particle contains no nucleation sites which satisfy the above condition, it will remain as a single domain in saturation remanence, and will require a reverse field which aids  $H_d$  before domain walls appear. Such 'back-field' nucleation has been directly observed in iron whiskers<sup>13</sup>, in individual  $\text{Co}_2\text{Sm}$  particles<sup>6</sup> and in the titanomagnetites described here.

If a sizeable percentage of grains fail to nucleate in saturation remanence, then these same particles will contribute significantly to the remanence of the assemblage. Moreover, the 'single-domain-like' fraction of a sized assemblage will increase as the mean grain size of the assemblage decreases, as the average number of nucleation sites per particle will decrease as the grain's surface area diminishes. The exact relationship between the number of sites and the number of walls is not understood, because the number of sites which actually succeed in nucleating will depend on the sites available as well as the number of domains which an individual particle can contain. However, we can still propose a simple model for the contribution to  $J_{rs}/J_s$  from particles which fail to nucleate in saturation remanence.

On the basis of the domain observations, it is first reasonable to assume that the nucleation sites are randomly distributed throughout a population of particles. Thus, the number of walls per particle in grains of a given size will vary probabilistically. Second, because nucleation sites vary in 'strength' according to whether or not the condition  $H_d \geq 2K/J_s$  is fulfilled, it is likely that the fraction of sites which nucleate in  $J_{rs}$  is small ( $\ll 1$ ). If nucleation can thus be defined to be a 'rare' event, then the number of walls per particle present in  $J_{rs}$  can be most simply described by a Poisson distribution.

Let  $w$  be the number of walls present in a grain of size  $L$  in  $J_{rs}$ , and let  $\lambda$  be the average number of walls, per particle, in  $J_{rs}$ . In general,  $\lambda$  will be a function of the grain size  $L$ . Therefore, the probability of there being  $w$  walls is

$$P(w) = \lambda^w e^{-\lambda} / w!$$

The contribution to  $J_{rs}/J_s$  from particles which do not nucleate in  $J_{rs}$  will be

$$J_{rs}(w=0)/J_{s,\text{total}} = e^{-\lambda} (J_{rs}/J_s)_{\text{SD}}$$

**Fig. 3** *a*,  $J_{rs}/J_s$  versus grain size in randomly oriented  $x = 0.6$  titanomagnetite. ●, Experimental data<sup>1</sup>; ○,  $P(w=0) (j_{rs}/j_s)_{SD}$ . *b*,  $J_{rs}/J_s$  versus grain size in randomly oriented Co-Fe alloy at 76 K (ref. 16). Grain size is normalized to superparamagnetic size  $D_p = 64 \text{ \AA}$ ; and  $D_{SD} = 286 \text{ \AA}$  (after ref. 16). ●, Experimental data; ▲,  $P(w=0) (j_{rs}/j_s)_{SD}$ .

where  $(j_{rs}/j_s)_{SD}$  is the ratio of saturation remanence to saturation magnetization for single-domain particles of the material under consideration.

Once  $\lambda$  is known, then the single-domain-like contribution to  $J_{rs}$  may be calculated as a function of grain size. Ultimately,  $\lambda$  must be experimentally determined, but it is possible to set an upper limit for  $\lambda$  as follows.

Kittel<sup>14</sup> predicted that the number of domains,  $n$ , contained by a cubic particle of length  $L$  should be

$$n = J_s(1.705L/\gamma)^{1/2}$$

where  $J_s$  is the spontaneous magnetization (G);  $\gamma$ , the specific wall energy (erg cm<sup>-2</sup>); and  $L$  the grain size (cm). This relationship has been verified for  $x = 0.55$  titanomagnetite<sup>15</sup>. Because this calculation minimizes the sum of wall and demagnetizing energy without considering the magnetization state or nucleation difficulties, we will set  $\lambda_{\max} = J_s(1.705L/\gamma)^{1/2} - 1$ .

The single-domain size  $L_{SD} = \gamma/(1.705J_s^2)$  by the Kittel calculation, so that

$$J_{rs}(w=0)_{\min}/J_{s,\text{total}} = \exp[-(L/L_{SD})^{1/2} + 1](j_{rs}/j_s)_{SD}$$

This model therefore gives the minimum contribution to  $J_{rs}/J_s$  from the particles which fail to nucleate in an assemblage of identical particles with grain size  $L$ .

This model has been compared to  $J_{rs}/J_s$  in randomly oriented grains of  $x = 0.6$  titanomagnetite, measured by Day<sup>1</sup>. The single-domain size is estimated to be  $1.4 \mu\text{m}$ , at which the experimental value of  $J_{rs}/J_s = 0.5$ . This estimate is consistent with that of Soffel for  $x = 0.55$  titanomagnetite<sup>15</sup>. Figure 3a shows that there is good agreement between the model and the data in the PSD range. The model ceases to be important above  $20 \mu\text{m}$  where the grains are truly multidomain.

In Fig. 3b the model has been compared to  $J_{rs}/J_s$  in randomly oriented Co-Fe alloy particles at 76 K, after Kneller and Luborsky<sup>16</sup>.  $J_{rs}/J_s$  is normalized with respect to the single-domain value of 0.46. Again, the model accounts for nearly all of  $J_{rs}/J_s$  in the PSD region which, for this material at 76 K, lies approximately between 300 and 1,300 Å.

The present domain observations indicate that, at least in  $x = 0.6$  titanomagnetite, a major contribution to PSD saturation remanence is due to the single-domain remanence of particles which fail to nucleate domain walls in this magnetization state. The present model agrees well with the grain-size dependence of  $J_{rs}/J_s$  in two very different magnetic materials, thereby indicating that nearly all of the saturation remanence in the PSD range may be due to particles that do not nucleate walls in this state. The observations and the model suggest that the remanence stored by domain wall displacement is of minor importance in the PSD range, and is significant only when the particles are truly

multidomain. However, additional domain observations are in progress to test the validity and generality of the model, as well as its applicability to other aspects of PSD behaviour such as the size-dependence of coercivity and weak-field TRM.

We thank Professor Dr H. Soffel for details of his ionic polishing technique.

## Implications for the primitive atmosphere of the oxidation state of Earth's upper mantle

R. J. Arculus & J. W. Delano

Research School of Earth Sciences, Australian National University, PO Box 4, Canberra, ACT 2600, Australia

Knowledge of the oxidation state of the Earth's mantle is critical for understanding the processes of magma genesis and the composition of deep-seated volatiles. Measurements reported here of the intrinsic oxygen fugacities ( $f_{O_2}$ ) of mantle-derived spinels from peridotite and megacryst assemblages show that the Earth's upper mantle is close to the synthetic iron-wüstite (IW) buffer curve in  $f_{O_2}$  versus  $T$  space. It seems likely that most erupted volcanics are oxidized after their formation, perhaps by diffusive  $H_2$  loss<sup>1</sup>. There is a strong possibility that the mantle was in equilibrium with a core-forming metal phase, and that subsequent oxidation of the upper mantle resulted from an interaction between the present oxidizing atmosphere-hydrosphere and the mantle by subduction processes. Evidence in support of this mechanism has been supplied by rare-gas analyses of deep-seated nodules from kimberlites<sup>2</sup>.

The gas species composing the early terrestrial atmosphere that formed through the degassing of the mantle having an oxygen state close to IW would have been profoundly different from those gases emitted from present-day volcanoes. The early primitive atmosphere would have been dominated by  $H_2$ ,  $CH_4$ ,  $CO$  and  $H_2S$  (that is reduced) rather than by the present-day, oxidized assemblage of  $H_2O$ ,  $CO_2$  and  $SO_2$ .

It has generally been assumed that the abundance ratios of gases emitted by recent volcanic activity reflect equilibrium with the sources of erupted magmas<sup>3</sup>, and that these relative abundances have remained essentially unchanged through geological time<sup>4-6</sup>. These assumptions have led to the supposition that the oxidation state of the Earth's upper mantle is, and always has been, close to the  $f_{O_2}$  defined by the quartz-fayalite-magnetite (QFM) buffer at any given temperature<sup>7,8</sup>.

Oxygen ion-specific properties of stabilized, solid  $ZrO_2$  electrodes<sup>1,9</sup> can be used to measure the oxidation state of mantle-derived materials directly. By modifying the published techniques<sup>9</sup> we have improved the precision, accuracy and reversibility of  $ZrO_2$  cell signals obtained<sup>10,11</sup>. Our approach involves isolating the e.m.f. signal generated by the sample from that unavoidably imposed by the residual atmosphere inside the sample-bearing cell. By varying the  $f_{O_2}$  of the residual atmosphere inside the cell, it is possible to determine a 'plateau' value of constant  $f_{O_2}$  relative to an external furnace atmosphere which represents a reversed, intrinsic  $f_{O_2}$  measurement for the sample alone. The extent of the plateau reflects the innate  $O_2$ -buffering capacity of the sample relative to the residual atmosphere. All previous measurements of intrinsic  $f_{O_2}$ s of geological samples have failed to achieve true reversals of the cell signals, and the published data<sup>1,9,12-14</sup> must represent upper, oxidized limits to the true values.

Our techniques have been used to measure the intrinsic  $f_{O_2}$  of spinels from peridotite and megacryst assemblages from Victoria (Australia), Arizona (US) and West Germany. These peridotite samples are considered to be representative of portions of the upper mantle in the pressure range  $\approx 20$ –25 kbar, whereas the spinel megacrysts are believed to be high-pressure ( $\geq 10$  kbar) equilibrium cumulates from basaltic magmas<sup>15,16</sup>. The major element compositions of the peridotites are similar to samples from the same region of Victoria and Dreiser Weiher described by Frey *et al.*<sup>17</sup> and Jagoutz *et al.*<sup>18</sup> as somewhat depleted in basaltic components.

The intrinsic oxidation states relative to the IW buffer range from  $\approx 0.25 \log_{10} f_{O_2}$  units more oxidized to 1  $\log_{10} f_{O_2}$  unit more reduced (Fig. 1). The overall reduced nature of the spinels, as well as the considerable range of  $f_{O_2}$ s obtained, are striking features of the data. We note that recent electrochemical cell data obtained by Ulmer *et al.*<sup>12</sup> on upper mantle-derived olivines plot close to the IW buffer, but the true values must be more reduced than that in view of the experimental technique. Figure 1 also shows  $f_{O_2}$  plotted against  $T$  for common basic eruptive rocks determined from analysis of coexisting Fe-Ti oxide minerals<sup>19</sup>. The difference of  $\sim 4 \log_{10} f_{O_2}$  units between the oxidation states of peridotites and igneous rocks may be due to late-stage oxidation of the latter, perhaps by  $H_2$  loss<sup>1</sup>. Alternatively the generation of magma in the upper mantle might involve a precursor, metasomatizing event<sup>20,21</sup> that causes localized oxidation and lowering of solidus temperatures relative to the bulk of the mantle. Limited data on the intrinsic  $f_{O_2}$  of kimberlite<sup>22</sup> suggest that some mantle-derived magmas may be as oxidized as values of  $f_{O_2}$  equivalent to QFM. In general, however, the proposed mechanism of  $H_2$  loss by magmas at shallow depths within the Earth is the favoured explanation for the contrast in oxidation states of erupted and deep-seated rocks due to the highly reduced nature of the spinel megacrysts from Arizona, and a deep-sea Hawaiian basalt<sup>1</sup> (Fig. 1).

We have noted<sup>10,11</sup> that the intrinsic  $f_{O_2}$  of a spinel peridotite sample from Australia is only  $\approx 2 \log_{10} f_{O_2}$  units more oxidized than that required for saturation with a potential core-forming Fe-Ni alloy. If oxygen is the main contributor towards lowering of the mean atomic weight of the Earth's core<sup>23</sup>, rather than S

Fig. 1  $f_{O_2}$  versus  $T$  data for common basic eruptive rocks compared with electrochemical cell determinations of intrinsic  $f_{O_2}$ s for plutonic and one volcanic rock. The dots outline the area of  $T$  versus  $f_{O_2}$  space in which  $>95\%$  of the available data for basic volcanic rocks fall<sup>7</sup>. S and B represent the intrinsic  $f_{O_2}$ s and  $T$ s recorded for specific horizons in the Stillwater<sup>9</sup> and Bushveld<sup>13</sup> intrusions. The line for the Hawaiian tholeiite is data obtained by Sato<sup>9</sup> for a submarine basalt on the flanks of Kilauea. Given the experimental techniques used for S, B and the Hawaiian tholeiite, these earlier data must represent the upper (oxidized) limits of the true intrinsic  $f_{O_2}$ s of the samples. Our data for one spinel peridotite from West Germany fall very close to the curve for Hawaiian tholeiite. Geronimo spinels are megacryst samples from Arizona while spinel 271 is from Victoria, Australia. Buffers: MW, magnetite-wüstite; Ni-NiO, nickel-nickel oxide; IW, iron-wüstite; QFM, quartz-fayalite-magnetite.

(ref. 24) or Si (ref. 25), then the values of intrinsic  $f_{O_2}$  reported here for portions of the Earth's upper mantle must be even closer to those required for equilibrium with the core. During the separation of a core-forming metal phase from the proto-mantle, an equilibrium of the sort described by

would buffer the  $f_{O_2}$  of the system, at least at low pressures ( $<100$  kbar). At higher pressures, phases other than orthopyroxene and olivine would be involved and the disproportionation of  $Fe^{2+}$  to  $Fe^{3+}$  and Fe metal would be a significant redox control<sup>26</sup>.

The variation in  $f_{O_2}$ s for mantle-derived samples collected from widely separated locations on the Earth could be due either to (1) the persistence of primary accretional heterogeneities in the Earth that have lasted for 4,600 Myr or (2) localized oxidation of the mantle following the onset of plate-tectonics.

The development of subduction as a major terrestrial tectonic feature raises the possibility that volatiles (for example, seawater bound in hydrous minerals,  $CO_2$  in carbonates) and oxidized oceanic crust can be transported into the upper mantle causing a progressive and irreversible oxidation of the Earth's upper mantle, especially at shallow levels. While no consensus has emerged in the petrological debate over the involvement of the subducted slab as a source of volatiles and magmas at island arcs and collisional continental margins<sup>27-29</sup>, there is no doubt that devolatilization of the subducted slab must occur especially at pressures  $<25$  kbar (refs 30, 31). Because the upper layers of the subducted lithosphere reflect prolonged interaction with the atmosphere-biosphere-hydrosphere system, which is dramatically oxidized relative to the  $f_{O_2}$ s prevailing in the upper

mantle, contamination of the mantle by a subducted component is a plausible oxidation mechanism over geological time.

Since the studies of Rubey<sup>32</sup> and Holland<sup>33</sup> on the evolution of the atmosphere and hydrosphere, it has been assumed<sup>3</sup> that the present-day volcano-associated gas abundances constrain the oxidation state of the upper mantle to that equivalent to the QFM buffer. This assumption, together with the supposed overabundance of siderophile elements in the upper mantle<sup>3</sup>, have led to conclusions that the mantle was never in equilibrium with a core-forming metallic phase. We have proposed<sup>34</sup> that the relatively high abundances of siderophile elements in the mantle (for example, Ni, Co, Pt group metals, W, Mo, Sn, Ag, Sb, Cu) can be explained by a combination of early equilibrium between a metal-silicate-sulphide system, and incomplete separation of sulphide into the core-forming metal, followed by meteoritic contamination<sup>35</sup> after core separation ( $\approx 4,500$  Myr). As at low  $f_{O_2}$ s and relatively high  $f_{S_2}$ , a significant proportion of the siderophile elements are partitioned into the sulphide phase, the supposed overabundance of siderophile elements in the mantle does not negate the possibility of core-mantle equilibrium.

Assuming a mantle close to the IW buffer in terms of oxidation state, it is possible to compute the nature of the gas species in the system C-O-H-S that would be in equilibrium with Fe-Mg silicates and oxides<sup>36-38</sup>. If the Earth's interior was an effectively closed system with respect to gaseous constituents during the earliest stages of planetary differentiation, then the volatile species residing in the mantle after core formation would have been in chemical equilibrium with the core-mantle system. In these conditions, gas-species computations show that CH<sub>4</sub>, H<sub>2</sub>, H<sub>2</sub>S and CO become volumetrically significant with respect to H<sub>2</sub>O, CO<sub>2</sub> and SO<sub>2</sub> (refs 36-38). Although the latter species may remain collectively the most abundant, it is important to note that condensation and low-temperature, selective reaction of the primitive crust with H<sub>2</sub>O, CO<sub>2</sub> and SO<sub>2</sub> could have resulted in a strongly reducing primitive atmosphere composed of CH<sub>4</sub>, NH<sub>3</sub>, H<sub>2</sub>, CO and H<sub>2</sub>S with lesser amounts of H<sub>2</sub>O vapour and CO<sub>2</sub>. Diffusive loss of H<sub>2</sub> from the atmosphere<sup>39</sup>, together with the evolution of life that was initially promoted in this reducing environment<sup>40</sup>, has ultimately resulted in a progressive oxidation and alteration of the primitive atmosphere<sup>6</sup>.

We propose that during partial melting of the upper mantle to produce basaltic magmas, the intrinsic  $f_{O_2}$  prevailing in the melt-residue system is close to the IW buffer. However, as these magmas rise towards the Earth's surface, their systems become open by H<sub>2</sub>-loss and interaction with the oxidized crust-hydrosphere-atmosphere resulting in oxidation levels in the vicinity of QFM. This is generally supported by the observation that magmatic systems are dominated by low-pressure equilibria<sup>41</sup>. While the oxidation state of the Earth's upper mantle is presently not in equilibrium with a metallic phase (the core), probably due to its contamination by oxidized, subducted components, it is significantly more reduced than the erupted magmas. Finally, our results on the intrinsic  $f_{O_2}$  of the Earth's upper mantle support the view that the early terrestrial atmosphere, which is known to have been formed by degassing of the Earth's interior, was strongly reducing relative to the present atmosphere and volcanic gases.

## Variations of ground radon concentrations with activity of Kilauea Volcano, Hawaii

Malcolm E. Cox, Kevin E. Cuff & Donald M. Thomas

Hawaii Institute of Geophysics, University of Hawaii, Honolulu, Hawaii 96822

Measurements of the concentration of the radioactive gas radon, in particular relative areal variations in Rn outgassing (mainly isotopes <sup>222</sup>Rn,  $t_{1/2} = 3.82$  days and <sup>220</sup>Rn,  $t_{1/2} = 54.5$  s), at shallow ground depths (30 cm) are being used extensively in Hawaii in the exploration for geothermal resources<sup>1,2</sup>. Zones showing a greater than usual degree of Rn ground gas outgassing have delineated areas of anomalous subsurface heat and increased permeability. The patterns of outgassing suggest that thermally induced ground gas convection systems have developed<sup>1</sup>. Nine measurement stations have been established on the upper east rift of Kilauea volcano along the Chain of Craters Road (Fig. 1) to observe: (1) temporal variations in Rn outgassing; (2) relationship between Rn outgassing and variations in seismicity; and (3) whether this technique can assist in understanding the 'plumbing' of Kilauea and whether monitoring of a larger number of stations could assist in indicating pre-eruptive activity. These nine stations, initially included in a summit-wide survey (August-September 1978), were re-established in October 1979 because of the increased seismic activity within the upper east rift. Fortunately, a small eruption of Pauahi Crater occurred on 16-17 November 1979 at the end of the first one-month period of measurement. The present results indicate that the Rn concentration increases before and during seismic events, then decreases before returning to a 'normal' value.

Variations of Rn concentration associated with changes in the activity of volcanoes and volcanically-induced earthquakes are most commonly reported from measurements of hot spring waters and fumarolic or spring gases<sup>3-6</sup>. These Rn values often have large fluctuations that cannot always be correlated with variations in volcanic or seismic activity. Rn measured in groundwaters on Karymsky volcano has, however, shown such correlation<sup>7</sup> and in Hawaii, widely spaced measurements on Kilauea's summit and east rift indicated increased ground Rn outgassing during periods of increased seismic activity associated with the September 1977 eruption of Kilauea<sup>8</sup>.

In the current survey, the concentrations of Rn in ground gas were measured by using  $\alpha$  particle-sensitive films (Kodak, LR 115, II) that were field exposed for periods of three to four

weeks<sup>1,9,10</sup>. To distinguish between the Rn contribution from soil immediately below the measuring device and Rn derived from a greater depth and transported by convection, the Rn emanation was measured in the laboratory by using one sample of soil from each station, and then was subtracted from the total measurement<sup>1,11</sup>. The Rn concentration units are  $\alpha$  tracks ( $T$ )  $\times 10^{-2} \text{ cm}^{-2} \text{ h}^{-1}$  (1 unit  $\approx 1.03 \times 10^{-4} \text{ nCi l}^{-1}$ ). The Rn emanation from the soil samples (all derived from tholeiitic basalt lavas) ranged from 0.5 to  $2.15 T \times 10^{-2} \text{ cm}^{-2} \text{ h}^{-1}$ . Duplicate laboratory measurements of Rn emanation from five different soil samples had a mean precision of  $\pm 3.5\%$ . Quadruplicate measurements in the field at one location gave a mean observed variation in corrected values of 10%. When these corrected field-measured concentrations at a station were lower than the Rn emanation from the soil at that location, the Rn concentrations are reported as negative values. Negative or very low positive values suggest that the flow of ground gas at that site is downward or, in some cases, static.

Areal variations in concentration measured during the summit-wide survey of Kilauea suggest that the long-term pattern on the summit is of strong outgassing within the caldera and associated major fractures, with a net downflow of ground gas in the peripheral area and on the upper flanks of Kilauea. This net downflow is, however, variable and responds to localized events such as described here, as well as being affected by the existence and location of faults and fractures that enable strong upflows to occur. The development of similar, but linear and areally restricted convection systems has also been observed over rift zones in Hawaii<sup>1</sup>.

The data for August 1978 were collected during a period of slow inflation in the Kilauea summit region<sup>12</sup>. This buildup of activity followed a flank eruption in the central east rift in September 1977. The Pauahi eruption of 16–17 November 1979 was a minor eruption that lasted  $\sim 22$  h and produced only a small volume of tholeiitic lava ( $\approx 700,000 \text{ m}^3$ ) at relatively low temperatures<sup>12</sup> ( $1,040$ – $1,080^\circ \text{C}$ ). Radon outgassing at the nine stations during August–September 1978 produced low positive values (Fig. 2). For the month up to and including the November 1979 eruption, values of Rn outgassing increased from 0.5 to 20.5 times the August–September 1978 measurements at seven of the nine stations (Fig. 2). The highest concentration was

The inset shows the location of the survey area on the island of Hawaii, and solid lines show the craters and the Chain of Craters Road; ●, measurement locations; ▲, vents of November 1979 Pauahi eruption; broken lines show faults and major fractures; small dots show the outline of the area of concentration of shallow epicentres (1–5 km) preceding the eruption<sup>12</sup>.

Fig. 2 Plot of Rn concentration at each station; each point is the value measured over an approximately four-week period and normalized to exposure time and surface area of film. The mean precision of the measurements was determined by field experiments to be  $\pm 5\%$ . a, 4 August–3 September 1978; b, 27 October–17 November 1979; c, 17 November–19 December 1979; d, 19 December 1979–15 January 1980; e, 15 January–6 February 1980; f, 6 February–27 February 1980; g, 27 February–20 March 1980; h, 20 March–10 April 1980; i, 10 April–3 May 1980.

recorded at Station F, next to an eruptive fissure that was active during the eruption of Hiiaka Crater in 1973. Rn outgassing was also high from a fracture associated with Puhimau Crater. This fracture extends to an area of steaming ground (between B and C), related to an intrusive event that occurred in 1938. At Stations B and E, Rn concentration before and during the eruption was 0.11 and 0.41 lower, respectively, than in August–September 1978. In the month following the Pauahi eruption, Rn concentration decreased significantly, mostly to negative values, at eight stations, and increased only at B. Stations A, F and H were monitored over the subsequent six months, and Station C was relocated and monitored over three months. During this latter period two episodes of seismic 'swarms' were significant. The first (2 March 1980) was located near Pauahi Crater, and the second (a week later) began in the same area and migrated  $\sim 6$  km eastwards (D. M. Moore, personal communication); these seismic events were probably caused by intrusive activity. At this time the summit was experiencing its fourth week of deflation.

Smaller changes in Rn concentration occurred in association with the seismic swarms. At Station H, the closest to the activity, the Rn concentration increased during the month before the events and decreased after them. (Note that this seismic activity occurred in the first part of the measurement period 27 February–20 March 1980). At Station F, the Rn concentration gradually decreased before and during these events, behaviour which was inverse to that at H and which is considered to be a result of localized convective ground gas flow related to the activity below Pauahi Crater. At Station C<sub>2</sub>, Rn concentrations remained much the same, but at A, concentrations increased to positive values during and immediately after these events, and then returned to negative values. This change is not fully

understood but could demonstrate some delay effect from the activity below Pauahi or possibly localized activity in the vicinity of Station A. Overall, Rn outgassing at three of the four stations underwent changes during the period of these seismic events, and subsequently returned to values apparently characteristic for each station.

We attribute the increases in outgassing associated with the eruption and the seismic events to various causes related to the movement of magma towards the surface and the associated deformation of the country rock. The rise of magma causes local temperature increases within the volcano and increases the fracture permeability. These conditions seem to permit Rn directly volatilized from the magma at high temperature to migrate towards the surface, transported by the escaping steam<sup>6,13,14</sup>. This steam and the overall thermally stimulated, increased outgassing act as a transport medium for other available Rn encountered during migration towards the surface<sup>1,7</sup>. The major sources of this additional Rn are the groundwater through which the vapour phases pass (Rn is more soluble in the vapour) and Rn within pore spaces and fractures in lava above the water table. A further source may be the decay of Ra within secondary mineralization (largely CaSO<sub>4</sub>) deposited on fracture surfaces in zones where hydrothermal activity has occurred<sup>1,15</sup>. Availability of minor quantities of Rn is possibly also enhanced by stress buildup and deformation, causing a greater diffusion of Rn by destruction of crystalline lattices of minerals and a greater pore space-transporting fluid area in contact at depth.

The common decrease in Rn concentration following the eruption and seismic swarms seems to be caused by depletion of Rn available in rock fractures and pores from 'flushing' by increased outgassing before and during these events. The Rn regenerates by decay of Ra and by diffusion into rock fractures over a period of several weeks, allowing an overall return to levels characteristic of periods of normal seismicity (no specific events). Similar post-eruptive Rn depletion was observed in thermal springs on Karymsky volcano<sup>4</sup> and has been proposed as creating <sup>226</sup>Ra-<sup>222</sup>Rn disequilibrium in pumice ejected during eruptions of Japanese volcanoes<sup>16</sup>. In both cases, a subsequent period of buildup was observed. In the case of ground Rn outgassing associated with an eruption, the post-eruptive reduction of near-surface heat and stresses at depth, partially decrease fracture permeability and allow the re-establishment of groundwater flow and consequent dissolution of much of the Rn being generated below the normal water table. After equilibrium conditions are again established, the greatest source of Rn to the surface is probably from the lava pile above the water table. The most important change, however, seems to be a reduction of thermally induced ground gas outgassing, which allows re-establishment of ground gas flow patterns. The greatest changes in outgassing were measured at stations close to fractures or faults below which there was magma migration, or other phenomena that produced increased seismic activity. Where Rn values at a station are atypical relative to adjacent stations (for example, B), they are apparently a consequence of localized ground gas convection systems developed around or between fractures. The flow of ground gas (whether upflow or downflow) in these systems is increased during these events, and in some cases, reversals in ground gas flow can occur usually within specific zones of fracturing.

Due to the apparent success of this study 25 stations (including the above) are now being monitored on the summit and along the east rift of Kilauea. The results from these stations reinforce the above findings, specifically, that the Rn concentration increases before and during seismic events (caused by either extrusive, intrusive, or earthquake activity) and decreases over several weeks after the event, then tends to return to a normal or characteristic value for each station. Atypical variations at some stations are indicated to result from location of fractures relative to each other and to the location of the event. Continuous monitoring of the larger number of stations will aid understanding of the fracture systems and the ground gas flow

patterns on the volcano, and may assist in indicating pre-eruptive activity.

We thank J. J. Naughton and D. B. Jackson for reviews and the staff of the Hawaii Volcano Observatory for cooperation. The study was carried out under US Department of Energy Contract no. EW-78-S-07-0713.

## Trophic structure of a grassland insect community

Blaine J. Cole

Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts 02138

The idea that there is some underlying trophic structure to ecological communities has long been attractive<sup>1-3</sup>. Energy, biomass or nutrients are undeniably transferred from one trophic level to another. However, does the number of species at one trophic level place constraints on the number of species at another trophic level? Cohen<sup>4</sup> has shown that, in a sample of 14 community food webs, the ratio of prey species to predator species remains virtually constant. In an analysis of a grassland insect community, Evans and Murdoch<sup>5</sup> have shown that the ratio of herbivorous insects to entomophagous insects remains fairly constant throughout the growing season. They speculated that this reflects an underlying trophic pattern that persists in the face of a continuing turnover of species. I have now found that a close examination of this pattern shows that an appearance of constancy can be generated by replicate samples taken from the pool of all available species.

The number of species of herbivorous and entomophagous insects in each sample interval may be envisioned as a random draw of species from the total pool of available species. In this case the number of herbivorous species would be a function of the total number of species drawn from the pool and the proportion of herbivorous species present in the species pool. The number of herbivorous species will have a hypergeometric distribution

$$P(k) = \frac{\binom{n}{n_1} \binom{n-n_1}{r-k}}{\binom{n}{r}} \quad (1)$$

Equation (1) gives the probability that exactly  $k$  herbivorous species will be found in a sample of  $r$  species taken from a total pool of  $n$  species of which  $n_1$  are herbivorous species. The expected number of herbivorous species in a sample of size  $r$  is given by

$$E(H) = r \left( \frac{n_1}{n} \right) \quad (2)$$

The variance of this expectation is given by

$$\text{Var}(H) = r \left( \frac{n_1}{n} \right) \left( 1 - \frac{n_1}{n} \right) \left( 1 - \frac{r-1}{n-1} \right) \quad (3)$$

**Table 1** The observed and expected numbers of herbivores in a grassland insect community

| Fortnightly interval | No. of species | Observed no. of herbivores | Expected no. of herbivores | Expected variance in herbivore no. |
|----------------------|----------------|----------------------------|----------------------------|------------------------------------|
| 1                    | 20             | 12                         | 12.4                       | 4.4                                |
| 2                    | 32             | 22                         | 19.9                       | 6.6                                |
| 3                    | 64             | 40                         | 39.7                       | 10.8                               |
| 4                    | 92             | 62                         | 57.1                       | 12.6                               |
| 5                    | 116            | 77                         | 72.0                       | 12.7                               |
| 6                    | 137            | 88                         | 85.1                       | 11.7                               |
| 7                    | 147            | 98                         | 91.3                       | 10.8                               |
| 8                    | 150            | 95                         | 93.2                       | 10.5                               |
| 9                    | 133            | 79                         | 82.6                       | 12.0                               |
| 10                   | 144            | 91                         | 89.4                       | 11.1                               |
| 11                   | 127            | 78                         | 78.9                       | 12.3                               |
| 12                   | 98             | 64                         | 60.9                       | 12.8                               |
| 13                   | 52             | 29                         | 32.3                       | 9.5                                |
| 14                   | 22             | 18                         | 13.7                       | 4.8                                |

The data from the 14 sample intervals of Evans and Murdoch specify all quantities of equations (2) and (3). The number of species is the quantity  $r$ . Other quantities are given in the text. The fit of observed values to theoretical expectations is tested by a  $\chi^2 = 3.45$ , d.f. = 13,  $P > 0.995$ .

The data from the 14 fortnightly intervals given by Evans and Murdoch are shown in Table 1. The total number of herbivorous and entomophagous species in this grassland community is given as 131 and 80, respectively. This represents values of  $n = 211$  and  $n_1 = 131$ . All values of equations (2) and (3) are known and thus the expected number of herbivores and the expected variance can be calculated.

Figure 1 shows the observed number of herbivores and the expected number of herbivores. Points fall on the line if the expected number of herbivores equals the observed number. The bars through the points are 2 s.d. from the expected values. All but one of the points (fortnightly interval 7) lie within 2 s.d. of the expected value.

There seems to be no systematic tendency in the samples to lie either above or below the line. Four samples are found to have more herbivores than expected, 10 have fewer than expected. The two-tailed binomial probability for this, or a more deviant event, is  $P = 0.284$ .

There does not seem to be any trend in deviation from the expected as one considers various numbers of species. Two of the four values greater than expectations are above the median of total species, two of the values are below the median. When there are few species, at either the beginning or end of the

**Fig. 1** The expected number of herbivores is plotted against the observed number of herbivores. The bars represent 2 s.d. from the expected number of herbivores.

season, there does not seem to be any less trophic structure. Nor does there seem to be more trophic structure during the period of greatest species diversity.

In conclusion, there does not seem to be any evidence that the ratio of herbivores to predators in this grassland insect community is maintained at a constant level by any other force than a statistical one. Analysis at another, deeper, level, well beyond the scope of this report, might ask why the ratio of herbivorous insects to their predators is 1.64. Given that it is, however, no further evidence for trophic structuring exists.

## Co-transfer of determinants for hydrogenase activity and nodulation ability in *Rhizobium leguminosarum*

N. J. Brewin\*, T. M. DeJong†, D. A. Phillips† & A. W. B. Johnston\*

\*John Innes Institute, Colney Lane, Norwich NR4 7UH, UK

†Department of Agronomy and Range Science, University of California, Davis, California 95616

In all organisms that fix atmospheric nitrogen a by-product of the nitrogenase reaction is hydrogen gas<sup>1</sup> which may dissipate up to one-third of the energy flux through nitrogenase<sup>2</sup>. Some nitrogen-fixing bacteria, including certain strains of the root nodule bacterium *Rhizobium*, possess an active hydrogen uptake (Hup) system permitting hydrogen to be re-cycled<sup>3,4</sup>. For this reason Hup<sup>+</sup> *Rhizobium* strains are thought to be more energy-efficient symbionts than their Hup<sup>-</sup> counterparts<sup>5-8</sup>. We report here that determinants for hydrogenase activity (*hup*) in a particular strain of *R. leguminosarum* (128C53) are genetically linked to determinants for nodulation ability (*nod*), and are probably carried on a plasmid, pRL6JI, of molecular weight (MW) ~19 × 10<sup>7</sup>. Although pRL6JI was not self-transmissible, the determinants for nodulation ability and hydrogenase activity (*hup*) could be transferred to other strains of *R. leguminosarum* after recombination with a derivative of a transmissible *R. leguminosarum* plasmid.

Nodulation ability is plasmid-determined in *R. leguminosarum*<sup>9-12</sup> and several determinants for nodule formation and function may be carried on a single plasmid<sup>11-15</sup>. We therefore attempted to transfer determinants for nodulation ability from strain 128C53, a Hup<sup>+</sup> field isolate of *R. leguminosarum*<sup>8,16</sup>, into a non-nodulating (Nod<sup>-</sup>) mutant of the Hup<sup>-</sup> field-isolate *R. leguminosarum* strain 300 in the hope that determinants for Nod<sup>+</sup> and Hup<sup>+</sup> were genetically linked and might consequently be co-transferred. The recipient strain was 16015, a derivative of strain 300, which contains *str-37* and *spc-54* markers and a plasmid deletion in a region determining nodule formation (Nod<sup>+</sup>) and nodule function (Fix<sup>+</sup>)<sup>11-13</sup>.

Strain 128C53 contains two large plasmids (MW ~19 and 23 × 10<sup>7</sup>) but no evidence for self-transmissible plasmids was obtained using methods which had identified such plasmids in other *Rhizobium* strains<sup>9,14,17</sup>. Therefore two self-transmissible plasmids, which did not themselves suppress the Nod<sup>-</sup> phenotype of strain 16015 but which were known to mobilize nodulation plasmids from other strains<sup>13</sup>, were introduced into strain 128C53. The transmissible plasmids used were pVW3JI and pVW5JI, kanamycin-resistant derivatives of pRL3JI and pRL4JI respectively<sup>13</sup>.

**Table 1** Co-transfer of Nod<sup>+</sup> and Hup<sup>+</sup> determinants from derivatives of strain 128C53 to strain 16015 following recombination with transmissible plasmids determining kanamycin resistance

*a*, Introduction of transmissible plasmids into 128C53 derivatives; *b*, transfer of plasmid-linked determinants from 128C53 derivatives to the non-nodulating strain 16015; *c*, control crosses: direct transfer of plasmids from 300 derivatives to strain 16015. Two derivatives of strain 300, each carrying a different transmissible plasmid conferring kanamycin resistance, were mated with strain 3854, a spontaneous *rif* mutant of strain 128C53 (itself a Hup<sup>+</sup> field isolate of *R. leguminosarum*). The genotypes of the donor strains were as follows:— 2515:300 *phe-1 ade-27 rif-45* pVW3JI; 2517:300 *phe-1 ade-27 rif-45* pVW5JI. Kanamycin-resistant derivatives of 3854 (128C53 *rif-397*) were obtained by introducing pVW3JI or pVW5JI into this strain and these derivatives were termed 3856, 3957 respectively (*a*). These two strains, together with the corresponding strain 300 donors were used in crosses to the Nod<sup>−</sup> strain 16015 (*b* and *c*). Kan<sup>r</sup> derivatives of 16015 were repurified and scored for nodulation ability on duplicate peas, var. Wisconsin Perfection. Roots of nodulated plants were tested for acetylene reduction (Fix<sup>+</sup>) and for the incorporation of tritiated hydrogen gas (Hup<sup>+</sup>) into the aqueous phase as described in Table 2.

When the 128C53 derivatives into which pVW3JI or pVW5JI had been introduced were used as donors to strain 16015, transfer of *kan* occurred at low frequency ( $10^{-6}$  to  $10^{-7}$  per recipient). However, more than half of the 16015 transconjugant clones were now able to nodulate peas (Table 1). In all cases the nodules formed had hydrogenase activity comparable to that for strain 128C53 and the rate of hydrogen evolution was correspondingly diminished compared with a Hup<sup>−</sup> strain (Table 2).

Because strain 300 itself is Hup<sup>−</sup> and neither Nod<sup>+</sup> nor Hup<sup>+</sup> phenotypes are conferred by pVW3JI or pVW5JI (data not shown), both Nod<sup>+</sup> and Hup<sup>+</sup> determinants must have been derived from strain 128C53 and must therefore be genetically linked in that strain. This was confirmed in further crosses between the 16015 Kan<sup>r</sup> Nod<sup>+</sup> Hup<sup>+</sup> transconjugants and strain 6015 (which carries the same *nod-6007* deletion as strain 16015<sup>9</sup>; in these crosses *kan* was transferred at high frequency ( $5 \times 10^{-3}$  per recipient) and most (22/25) of the Kan<sup>r</sup> 6015 transconjugants were also Nod<sup>+</sup>. In all cases Nod<sup>+</sup> transconjugants were Hup<sup>+</sup>. The very high-frequency co-transfer of *nod* and *hup* with *kan* suggests that there has been genetic recombination between these markers, and the high-frequency transfer of *kan* suggests the involvement of a plasmid, at least at this stage.

The transfer frequency of *kan* from the 128C53 derivatives to strain 16015 was inexplicably low but was at least 10-fold higher than for transfer of chromosomal alleles (data not shown). When similar crosses were performed using the P1 group R plasmid pJB3JI (which confers tetracycline resistance<sup>14</sup>), the Tet<sup>r</sup> determinant was transferred into and out of strain 128C53 at normal frequencies ( $10^{-2}$ – $10^{-3}$ ), but no co-transfer of Nod<sup>+</sup> to strain 16015 was observed (data not shown).

Because the Nod<sup>+</sup> determinants of strain 128C53 were probably plasmid-borne, the plasmids from many of the strains described here were examined after electrophoresis on agarose gels (Fig. 1). In strain 2515, a 300 derivative, the plasmid pVW3JI was visible as the second-fastest migrating band, MW  $13 \times 10^7$  (Fig. 1 track *a*, and see ref. 12). However, in all three Kan<sup>r</sup> derivatives of 128C53 examined after transfer of pVW3JI into this strain, no band corresponding to pVW3JI was visible (Fig. 1 track *c*): furthermore, the smaller of the two plasmids (MW  $19 \times 10^7$ ) visible in strain 128C53 (Fig. 1 track *b*) had also disappeared. An identical plasmid pattern was observed in Kan<sup>r</sup> derivatives of 128C53 obtained after the transfer of pVW5JI (MW  $16 \times 10^7$ ) into this strain. However, when the P1-group plasmid pJB3JI was transferred into strain 128C53 (Fig. 1, track *e*) the two resident plasmids of strain 128C53 remained visible and in addition there was a band corresponding in mobility to that of pJB3JI.

The simplest interpretation that is consistent with both the genetical and physical observations described is that the smaller plasmid of strain 128C53 is the likely carrier of the linked Nod<sup>+</sup> and Hup<sup>+</sup> determinants. We term this plasmid pRL6JI, and we propose that pRL6JI recombined (or co-integrated) with the introduced plasmid to form a transmissible plasmid carrying determinants for Nod<sup>+</sup> and Hup<sup>+</sup> from pRL6JI, Kan<sup>r</sup> from

**Fig. 1** Physical interaction between pVW3JI and a plasmid from strain 128C53. See Tables 1 and 2 for a description of the relevant strains. Lysates were prepared and analysed by electrophoresis on agarose gels following the method of Hirsch *et al.*<sup>12</sup>. In each track the fastest migrating band represents sheared (chromosomal) DNA. *a*, Strain 2515. The plasmid band corresponding to pVW3JI is the second-fastest migrating plasmid band. The two high molecular weight plasmids of strain 300 are just visible on this gel (see ref. 12). *b*, Strain 3854 = 128C53 *rif-397*. *c*, Strain 3856 = 3854 carrying *kan* determinant from pVW3JI. *d*, Strain 3892 = kan<sup>r</sup> Nod<sup>+</sup> Fix<sup>+</sup> Hup<sup>+</sup> transconjugant from the cross 3856 × 16015. *e*, Strain 3955 = 3854 pJB3JI. Two tracks have been removed from this gel corresponding to lysates from 3957 (pVW5JI derivative, identical to track *c*) and 16015 (identical to track *d*).

pVW3JI (or pVW5JI) and *Fix*<sup>+</sup> determinants from either or both moieties. The failure to detect the recombinant plasmid as a band on agarose gels might be due to the fact that its very large size ( $MW > 30 \times 10^7$ ) would make it too susceptible to breakage to be recovered intact in our plasmid preparations. Inter-plasmid recombination might have occurred if pRL6JI shared homologous sequences with pVW3JI and pVW5JI.

There are at least two explanations for the fact that the introduced plasmid was never observed in Kan<sup>r</sup> derivatives of strain 128C53. Either the introduced plasmids are incompatible with pRL6JI which itself might carry genes essential for the growth of this strain or, alternatively, pVW3JI or pVW5JI might be incapable of autonomous replication within this host. Both possibilities are consistent with the relatively low initial transfer frequency ( $10^{-4}$ ) of the transmissible plasmids into strain 128C53 and with the observed disappearance of the band corresponding to pRL6JI from Kan<sup>r</sup> transconjugants.

**Table 2.** Quantitative measurements of pea root nodule activity following inoculation with Hup<sup>+</sup> and Hup<sup>-</sup> strains of *R. leguminosarum*

| Inoculant  | Acetylene reduction<br>( $\mu\text{mole C}_2\text{H}_4$<br>per plant per h) | Hydrogen evolution<br>( $\mu\text{mole H}_2$<br>per plant per h) | Tritium incorporation<br>( $\mu\text{mole H-T}$ per<br>g-nodule fresh<br>wt per h) |
|------------|---|--|--|
| 300        | 5.11 ( $\pm 0.32$ )   | 3.16 ( $\pm 0.23$ )  | 0.002 ( $\pm 0.001$ )  |
| 300 pRL3JI | 8.81 ( $\pm 0.77$ )   | 4.57 ( $\pm 0.69$ )  | 0.001 ( $\pm 0.001$ )  |
| 3740       | 8.46 ( $\pm 0.24$ )   | 5.01 ( $\pm 0.30$ )  | 0.001 ( $\pm 0.001$ )  |
| 128C53     | 7.97 ( $\pm 0.99$ )   | 0.57 ( $\pm 0.20$ )  | 0.738 ( $\pm 0.063$ )  |
| 3892       | 6.84 ( $\pm 0.48$ )   | 0.32 ( $\pm 0.04$ )  | 1.013 ( $\pm 0.112$ )  |
| 3894       | 9.43 ( $\pm 1.09$ )   | 0.37 ( $\pm 0.04$ )  | 0.844 ( $\pm 0.074$ )  |

'Alaska' peas grown in modified Leonard-jar assemblies were assayed 25 days after inoculation as previously described<sup>8</sup>. Tritium incorporation by nodulated roots was measured in 25-ml incubation vessels containing tritiated hydrogen gas (2.4%, v/v,  $2.4 \text{ mCi mmol}^{-1}$ ) in the presence of acetylene (10%, v/v) to inhibit hydrogen production by nitrogenase<sup>8</sup>. Incubation was for 30 min and means ( $\pm$  s.e.) were computed for six replicates. Bacteria recovered from surface-sterilized nodules were tested for the appropriate drug-resistance markers and plasmid patterns. Strains 3740, 3892 and 3894 were all Nod<sup>+</sup> Kan<sup>r</sup> derivatives of strain 16015. In strain 3740, which was Hup<sup>-</sup>, *kan* was derived from pVW5JI and *nod* from strain 300 (see ref. 13 for the construction of this strain). In strains 3892 and 3894, *kan* was derived from pVW3JI and pVW5JI respectively, *nod* and *hup* determinants were derived from 128C53 (see Table 1).

The plasmids of the 300 Nod<sup>-</sup> strain 16015 have already been described<sup>12,14</sup>. In the Kan<sup>r</sup> derivatives that were Nod<sup>+</sup> Hup<sup>+</sup>, no new plasmid bands could be seen (Fig. 1 track d). This implies either that any co-transferred plasmid co-migrated on gels with a resident plasmid from strain 16015 or that the co-transferred plasmid was too large to be visualized on gels (as was suggested for the donor strain itself). However, Kan<sup>r</sup> 16015 derivatives that were Nod<sup>-</sup> (Table 1b) contained a new plasmid band present in neither strain 16015 nor in the donor strain, but corresponding in size to the original plasmid band of pVW3JI as seen in lysates of normal strain 300 derivatives (Fig. 1 track a). In these cases it seems that the original pVW3JI plasmid may have been regenerated by a reversal of the original recombination event that caused its disappearance from derivatives of 128C53.

We have demonstrated that two apparently unrelated symbiotic phenotypes, nodulation ability for peas and the presence of hydrogenase activity, are genetically linked in strain 128C53. It is possible that a large proportion of the genes concerned specifically with the nitrogen-fixing symbiosis, the so-called symbiotic genes, will be found to be clustered and located on one or a few plasmids. Such an arrangement would certainly make it easier to develop genetically improved strains of *Rhizobium*.

This work was supported in part by NATO grant 1533 and by US NSF grant PFR77-07301. We thank Dr M. G. Yates and Professor J. R. Postgate for help and advice on the measurement of tritium incorporation by root nodules, Miss E. A. Wood for technical assistance, and Professor D. A. Hopwood for criticism of the manuscript.

**Note added in proof:** A. H. Christensen and K. R. Schubert (personal communication) have informed us that their culture of 128C53 (obtained from Dr J. C. Burton) has a different plasmid profile from that described here for our culture of this strain. It is not clear whether our Hup<sup>+</sup> strain has undergone plasmid rearrangements during its history or whether two different strains exist bearing the designation 128C53.

## Nonrandom segregation of nucleolar organizing chromosomes at mitosis?

Martin Bobrow & Jane Heritage

Department of Medical Genetics, Old Road, Headington, Oxford OX3 7LE, UK  
Genetics Laboratory, Oxford University, South Parks Road, Oxford OX1 3BD, UK

The random assortment of non-homologous chromosomes at meiosis is one of the fundamental tenets of genetics, to which few exceptions have been documented<sup>1</sup>. The segregation of mitotic chromatids is believed to be similarly random. We report here that we seem to have discovered a new exception to this rule, in that nucleolar organizing chromosomes remain associated with one another, held in the same lateral orientation, for several mitotic cycles.

Five pairs of human chromosomes (nos 13, 14, 15, 21 and 22) carry rDNA sequences in specific chromosome segments, known as nucleolar organizing regions (NORs). The chromosomes are all acrocentrics, and the NORs are on their short arms. More than one chromosome may participate in the formation of a single nucleolus, DNA from their NORs uncoiling and extending deep into the substance of the nucleolus<sup>2</sup>. During mitosis, the nucleoli disappear, but the chromosomes may be seen at metaphase grouped together with their short arms in close proximity. These configurations are called 'satellite associations' (ref. 3). A very close association of nucleoprotein complexes between associated chromosomes has been demonstrated autoradiographically<sup>4</sup>.

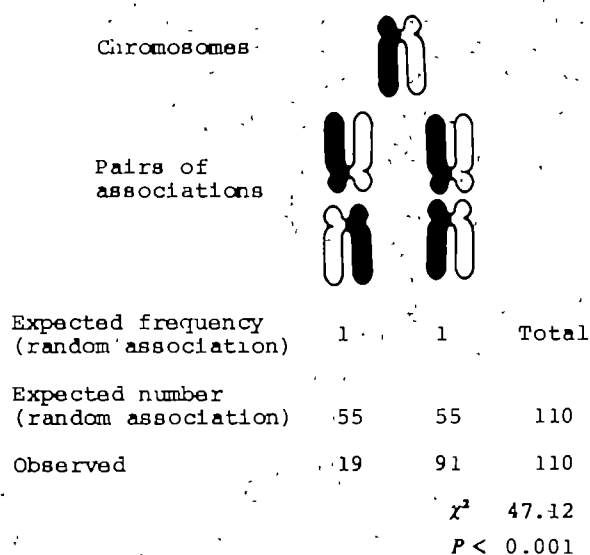

Fig. 1 Expected and observed satellite-association pairs in second-generation BUdR-substituted cells.

Methods have recently been developed which differentially stain the two chromatids of each chromosome. Cells grown in the presence of bromodeoxyuridine (BUdR) incorporate this base into their DNA in place of thymidine, and such BUdR-substituted chromatids stain less intensely with the dye 33258-Hoechst<sup>5</sup>, or with a combination of 33258 and Giemsa<sup>6</sup>. By growing cells in BUdR-containing medium for two cell cycles, chromosomes are produced with one-chromatid half-substituted and one fully substituted with BUdR. The 'old' and 'new' chromatids can be differentially stained. After a third round of

DNA replication in the presence of BUdR, one-quarter of the chromatids will still be thymidine containing and darkly stained; half of the chromosomes will therefore have differentially stained chromatids, and the other half will consist of two bifilarly substituted, poorly stained chromatids.

We have examined satellite-associated chromosomes in both second- and third-generation BUdR cells, using standard peripheral blood chromosome cultures from five normal people. (Similar observations were made on a culture from an orangutan, although these cells are not included in the totals scored.) To minimize subjective scoring bias, we selected satellite associations consisting of only two chromosomes, where the chromosomes were closely paired (less than about 1 chromatid width apart), directly end-on to one another, and reasonably straight. All such configurations were scored. In second-generation cells, either a dark-to-dark or dark-to-light chromatid alignment may be seen, and assuming random segregation of chromatids at mitosis, these should be equally common. Our observations on 110 associations are set out in Fig. 1. It is clear that there is a highly significant tendency for old, thymidine-containing, darkly staining chromatids to be aligned with one another. There is about a 17% frequency of discordant (dark-to-light) associations. This may be an underestimate of stability, as many of the 17% exceptional associations seemed to be minimally twisted, but these were, nevertheless, scored as 'discordant' to avoid any possibility of artificially inflating the rate of concordant segregation.

In the absence of sister chromatid exchanges near the centromere, metacentric chromosomes generally show the dark-staining strand to go straight, rather than diagonally, across the centromere. In a purely descriptive sense, pairs of associated acrocentric chromosomes are behaving like single metacentric chromosomes with a centromere breakage rate of ~17% per cell cycle.

It is similarly simple to define the expected frequencies of various configurations in third-division cells, on the assumption either of random assortment or of a given dissociation rate per

Fig. 2 Expected and observed satellite-association pairs in third-generation BUdR-substituted cells. If association pairs dissociate at the rate 'p' per cell cycle, and single chromosomes reassociate at random, the frequencies of the four classes of association after three cell cycles can be calculated as:

$$\text{Class 1} = \frac{1}{8}(4 - 7p + 6p^2 - 2p^3)$$

$$\text{Class 2} = \frac{p}{8}$$

$$\text{Class 3} = \frac{1}{8}(3p - 3p^2 + p^3)$$

$$\text{Class 4} = \frac{1}{8}(2 - 3p + 3p^2 - p^3)$$

The 'expected' values in the last line of the figure are derived by substituting  $p = 0.2$  in these formulae. NS, not significant.

cell cycle with random rejoining of dissociated chromosomes. These expectations, and our observations on 50 relevant associations, are set out in Fig. 2. The data clearly fit well with the observations on second-division cells.

The staining of a chromatid in this system depends on the presence of either thymidine or BUdR in a single DNA strand. Similar staining of opposed chromatids therefore implies that they are being held in alignment during mitosis by forces operating at the level of the single DNA strand.

There are several possible explanations for this phenomenon. (1) Chromatids of associated chromosomes may be held oriented relative to one another by the establishment of physical connectives within the nucleolar substance. The existence of ribonucleoprotein connections has been demonstrated<sup>4</sup>. Inter-chromosomal DNA connections have also been reported, and have led to suggestions of the same DNA strand continuing through more than one chromosome<sup>7</sup>, although there is now a strong suspicion that these interchromosomal fibres are artefacts<sup>8</sup>. Our observations require that single DNA strands are held together for several cell cycles, and it is easier to envisage such a rigid orientation from a nucleic acid connection than from mere enmeshment in a common nucleoprotein matrix. (2) One cannot exclude the possibility that chromatids do segregate randomly at mitosis, but that their involvement in new satellite associations is nonrandom, thymidine-containing chromatids selectively aligning opposite one another. Even this implies a pairing phenomenon at the level of the single DNA strand. The restrictions on joining imposed by DNA strand polarity would not adequately explain our observations, as the number of active nucleolus-organizing chromosomes per cell is such that there would almost always be both thymidine- and BUdR-containing strands of each polarity available. (3) Presumably, not all nucleolus-associated chromosome groups survive into metaphase as visible satellite associations, but there seems to be no reason that 'concordant' pairs should be more likely to survive than 'discordant' pairs.

Any attempt to choose between these possibilities, or to consider the basic mechanism of this phenomenon, would be purely speculative. However, the most economic hypothesis seems to be that a physical continuity, at the DNA single-strand level, is actually established between non-homologous chromosomes, and can persist through several cell cycles.

The most common form of chromosome rearrangement in man is the Robertsonian fusion, in which acrocentric chromosomes become permanently joined by their short arms, the translocation chromosomes sometimes remaining demonstrably dicentric. Such translocations may segregate to produce aneuploid offspring, particularly Down's syndrome. If the NOR-bearing chromosomes regularly establish physical connections with one another, this may be related to the generation of such translocations.

There are conflicting data on the randomness with which particular chromosomes are involved in satellite associations<sup>9</sup>, and on whether such associations are causally related to the production of trisomic children<sup>10-12</sup>. If such a relationship does exist, it may also be concerned with the phenomenon of intimate chromosome association described here.

We thank H. J. Evans for useful comments. This work was supported by a programme grant from the MRC.

## Human T lymphocytes of inducer and suppressor type occupy different microenvironments

George Janossy, Nicholas Tidman, Warwick S. Selby, J. Alero Thomas & Sylvia Granger

Department of Immunology, Royal Free Hospital School of Medicine, London NW3 2QG, UK

Patrick C. Kung & Gideon Goldstein

Ortho Pharmaceutical Corporation, Division of Immunobiology, Raritan, New Jersey 08869

Distinct subsets of human peripheral T-cell populations have recently been characterized using mouse monoclonal antibodies and conventional hetero-antisera in functional tests *in vitro*<sup>1-6</sup>. 'Inducer' or 'helper' T cells have been shown to react with a monoclonal antibody termed OKT4. These OKT4<sup>+</sup> cells respond to soluble antigens<sup>3</sup>, help B-lymphocyte differentiation into plasma cells in pokeweed mitogen stimulated cultures<sup>4</sup> and assist the development of cytotoxic T cells in mixed lymphocyte cultures (MLC)<sup>5</sup>. In contrast, the 'suppressor-cytotoxic' T-cell subset is recognized by the monoclonal antibodies OKT5<sup>5</sup> and OKT8<sup>6</sup>. The same subset can also be labelled with a conventional horse antiserum which (after extensive absorption) recognizes TH<sub>2</sub> antigen<sup>5,7</sup>. These OKT8<sup>+</sup>, TH<sub>2</sub><sup>+</sup> cells fail to respond optimally to soluble antigen<sup>3</sup> but contain the concanavalin-A induced suppressor cell population<sup>5,7</sup> and the cells which develop cytotoxic activity in mixed lymphocyte reaction (MLR)-induced cell-mediated lympholysis<sup>3</sup>. The physiological role, tissue distribution and recirculation patterns of 'inducer' and 'suppressor' T cells are unknown, although changes in the proportion and activity of blood-borne T-cell subsets have been observed in various immunoregulatory disorders<sup>8,9</sup>. We have therefore now analysed the distribution of these T-cell subsets in the lymphohaematopoietic organs and the gut. OKT4<sup>+</sup>, OKT8<sup>+</sup> cells of inducer type predominate in the thymic medulla, blood and T-cell traffic areas such as tonsillar paracortex and intestinal lamina propria. OKT4<sup>+</sup>, OKT8<sup>+</sup> cells of suppressor-cytotoxic type, on the other hand, constitute the larger part of T-cell population in normal human bone marrow and gut epithelium. Furthermore, a close micro-anatomical relation can be seen between the OKT4<sup>+</sup>, OKT8<sup>+</sup> T cells and non-lymphoid cells expressing large amounts of Ia-like (p 28, 33) antigens, for example, interdigitating (ID) cells and Ia<sup>+</sup> macrophages, suggesting that Ia-like antigens may play a part in the local regulation of inducer T cell activity. Thus the T-cell subsets which have been shown to have different functions *in vitro* seem also to have different patterns of tissue distribution, implying different immunological functions *in vivo*.

The principle of the study was to apply well characterized antibodies from different species in various combinations using second layer antibodies coupled with different fluorochromes (fluorescein-isothiocyanate FITC: green and tetramethylrhodamine isothiocyanate TRITC: red) in order to determine whether the antibodies detect identical, overlapping or distinct populations. Table 1 shows the distribution of OKT4<sup>+</sup> and OKT8<sup>+</sup>, TH<sub>2</sub><sup>+</sup> T lymphoid cells analysed in cell suspensions. Preliminary experiments showed that all three reagents (OKT4, OKT8 and anti-TH<sub>2</sub>) reacted exclusively with T-lymphoid cells which were identified with a rabbit antiserum reacting to human T-lymphocyte antigen (HuTLA<sup>+</sup>; Table 1). These findings confirmed that the antibodies were T-lineage markers<sup>1-6,10</sup>. Furthermore, the OKT8 and anti-TH<sub>2</sub> antibodies labelled the same populations (>98% double-labelled cells). Thus these two reagents were used interchangeably in this study.

In the human thymus 78% of all cells were OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> (see also refs 1–6). The majority (80%) of these double-labelled cells expressed nuclear terminal deoxynucleotidyl transferase (TdT), a marker of cortical thymocytes<sup>11</sup>. 20% of the OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> population was TdT<sup>+</sup>.

**Fig. 1** Cells in the human thymic cortex (c) and medulla (m) reacting with antisera to OKT8 (OKT8, a mouse monoclonal antibody), to human thymocyte/T-cell antigen (HuTLA; a rabbit antiserum) and to Ia-like p 28, 33 antigen (Ia; a chicken antiserum detecting core determinants of p 28, 33)<sup>11,12</sup>. Sections of frozen tissue biopsies from infant thymus were fixed for 10 min in ethanol and washed in saline<sup>11</sup>. OKT8 (1:100 dilution) and chicken anti-Ia-like antiserum (1:40) were added, incubated for 30 min at room temperature and washed for 30 min. Goat anti-mouse Ig-FITC (affinity purified antibody; 0.5 mg ml<sup>-1</sup>) and sheep anti-chicken Ig-TRITC (1:20 dilution) were added for 30 min and washed again. The same areas were photographed with filters for FITC (OKT8) and TRITC (Ia). The broken line indicates the cortico-medullary boundary. Insert shows the same area photographed in an adjacent section. This had been incubated with anti-HuTLA (1:20 dilution), washed and stained with goat anti-rabbit Ig-FITC (1:40 dilution). OKT8 reacts with virtually all cortical thymocytes and 20% of medullary thymocytes. Anti-HuTLA detects all thymocytes. Anti-Ia stains cortical epithelial cells strongly and large medullary cells corresponding to interdigitating cells (ID) very strongly.  $\times 200$ .

Within the population of thymic cells with only a single label (putative thymic medullary lymphocytes; see below), the OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> cells were more frequent (76%) than the OKT4<sup>+</sup>, TH<sub>1</sub><sup>+</sup> cells (24%). Previous studies<sup>1–6</sup> suggested that the majority of T cells in peripheral human blood are either OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> or OKT4<sup>+</sup>, TH<sub>1</sub><sup>+</sup>, although the existence of a few double-labelled cells has not been formally excluded. Our study has extended these previous findings (Table 1). The calculated proportions of OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> cells (inducer phenotype) within the HuTLA<sup>+</sup> T-lymphoid population were 66% in blood, 64% in tonsil and 13% in bone marrow from children. In contrast, the proportions of OKT4<sup>+</sup>, TH<sub>1</sub><sup>+</sup> cells (suppressor-cytotoxic phenotype) were 27% in blood, 20% in tonsil and 82% in bone marrow. A small number of double-labelled OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> lymphocytes were found in the periphery—2.6% of blood T cells and 6.5% of tonsil T cells. (These cells could have been immature T cells but they failed to express cortical thymocyte markers such as TdT and reactivity with monoclonal antibody to cortical thymocyte antigen, HTA-1<sup>11,12</sup>.) Thus the definition of 'inducer' and 'suppressor-cytotoxic' T subsets with the available reagents in man seems to be more convenient and distinct than the definition of corresponding cell types in the mouse where large proportions (20–50%) of peripheral T cells simultaneously express 'inducer' (Ly-1) and 'suppressor' (Ly-2,3) markers<sup>14,15</sup>.

**Fig. 2** Cells in the human tonsil reacting with antisera to OKT8 (OKT8), to immunoglobulin (Ig), to human T-cell/thymocyte antigen (HuTLA) and to Ia-like p 28, 33 antigen (Ia). GC, germinal centre, containing lacy deposits of immunoglobulin; ly corona, lymphocyte corona containing Ig<sup>+</sup> B lymphocytes; T, paracortical area with T cells which are HuTLA<sup>+</sup> (see insert); only 20% of these T cells react with OKT8. In this area large ID cells stain brightly for Ia (see insert). The reagent combinations were OKT8 (FITC) together with goat anti-human IgM (TRITC; a purified antibody used at 0.5  $\mu$ g ml<sup>-1</sup>), and HuTLA (FITC) with Ia (TRITC). The same areas were photographed with selective filters.  $\times 200$ .

An immunohistological analysis of T-cell subsets was performed using OKT8 antibody with an affinity purified goat anti-mouse Ig-FITC. Bright membrane staining was obtained on a subset of lymphoid cells in sections of frozen biopsies. The OKT8 antibody could also be used in double-marker combinations with rabbit anti-HuTLA antiserum and other reagents (Figs 1–3). Since the OKT4 antibody showed only weak staining in tissue sections of peripheral lymphoid organs, T-cell subsets of 'inducer' and 'suppressor-cytotoxic' type were defined as HuTLA<sup>+</sup>, OKT8<sup>+</sup> and HuTLA<sup>+</sup>, OKT8<sup>+</sup>, respectively.

In the thymic medulla, 60–75% of HuTLA<sup>+</sup> cells were OKT8<sup>+</sup> (Fig. 1). This is consistent with the cell suspension analysis discussed earlier (Table 1), indicating that the majority of mature thymic medullary lymphocytes express the 'inducer' phenotype. Note that some of the medullary OKT8<sup>+</sup> cells may be recent arrivals from the cortex which express TdT and cortical thymocyte antigen HTA-1<sup>11</sup>. These cells, which represent 6–15% of the medullary cell population, may not have

**Fig. 3** Cells in the human jejunum reacting with antisera to OKT8 (OKT8) and to human T-cell/thymocyte antigen (HuTLA). e, Epithelium; lp, lamina propria. (\*) intestinal lumen. Most intra-epithelial lymphocytes are double-stained for HuTLA and OKT8 ('suppressor-cytotoxic' phenotype). In the lamina propria many T cells are HuTLA<sup>+</sup>, OKT8<sup>+</sup> ('inducer' phenotype).  $\times 220$ .

10<sup>6</sup> cells in 50 µl buffered saline were incubated with conventional antisera (1:20 dilution) and monoclonal antibodies (peritoneal exudate; 1:200 to 1:500 dilution), washed twice and reincubated with goat anti-mouse-Ig-TRITC and goat anti-rabbit or horse Ig-FITC (1:20 dilution), followed by washing and counting the labelled cells under a fluorescence microscope.

\* A rabbit antiserum reacting with human thymocytes/T cells was made against monkey thymocytes and extensively absorbed (with human red cells, liver powder, chronic lymphoid leukaemia and lymphoid cell lines of B type and acute myeloid leukaemia; ref. 12). The second layer used (goat anti-rabbit-Ig) was conjugated to FITC. The horse anti-HuTLA prepared from an anti-human thymocyte globulin (ATGAM; Upjohn, Lot 17.923) with similar absorptions gave identical results. Values are mean ± s.e.m.

† These percentages are consistently lower than the proportion of HuTLA<sup>+</sup> cells in the same sample. The HuTLA<sup>+</sup>, OKT4<sup>+</sup>, TH<sub>2</sub><sup>+</sup> cells appear to be larger blasts in the thymus (prothymocytes? see refs 6, 11, 13) and small lymphocytes of unknown function in the blood and tonsils.

‡ Horse anti-TH<sub>2</sub> serum was prepared from horse anti-HuTLA serum at the Royal Free Hospital by further absorption with OKT4<sup>+</sup> leukaemic lymphocytes obtained from a patient with chronic lymphocytic leukaemia of T-cell type. This reagent gave identical results to the control horse anti-TH<sub>2</sub> reagent (see ref. 7).

§ Similar double-labelling experiments using anti-TH<sub>2</sub> and OKT8 showed that these two reagents reacted with an identical population of cells; >98% of labelled cells in thymus, blood and tonsil were reactive with both antisera.

|| Infant thymus cell suspensions from patients undergoing elective cardiac surgery.

¶ Normal donors of 30–42 years of age.

\* The donors (10–15 yr) had tonsillitis in the past. The tonsillectomy was performed after antibiotic treatment.

\*\* From children (5–15 yr). No haematological abnormality.

yet matured into OKT8<sup>-</sup> lymphocytes. There was an abundance in the medulla of non-lymphoid cells which strongly expressed Ia-like (p 28, 33) antigens. Some of these could be Ia<sup>+</sup> epithelial cells which were also present in the cortex. Nevertheless the most brightly stained population appeared to be a group of interdigitating (ID) cells with prominent veils and processes<sup>11,16</sup>. These Ia<sup>+</sup> cells could also be detected in the interlobular septae and may have been migrating cells (Fig. 4 and refs 11, 17).

In serial sections of tonsil the germinal centres (which contained lacy deposits of immunoglobulin complexes surrounded by a B-lymphocyte corona) and paracortical T-cell areas were identified (Fig. 2). In the B-lymphocyte corona less than 5% of cells were HuTLA<sup>+</sup>. This small T-lymphocyte population contained both OKT8<sup>+</sup> and OKT8<sup>-</sup> cells. In the paracortical areas 70–80% of HuTLA<sup>+</sup> cells were OKT8<sup>-</sup> and 20–30% were OKT8<sup>+</sup>. In these areas large ID cells expressed Ia-like antigens very strongly (Figs 2 and 4; see also refs 18–20). It appeared that the Ia<sup>+</sup> ID cells were preferentially surrounded by OKT8<sup>-</sup> T lymphocytes and tended to be apart from the OKT8<sup>+</sup> cells. Further studies will be needed to determine

whether isolated ID cells form rosettes with T lymphocytes of the 'inducer' or 'suppressor' phenotype.

Finally, histologically normal jejunal biopsies were studied from patients undergoing investigation of diarrhoea. In the lamina propria the HuTLA<sup>+</sup> population contained more OKT8<sup>-</sup> cells than OKT8<sup>+</sup> cells (65–75% OKT8<sup>-</sup> T cells in the three samples studied; Fig. 3). When adjacent sections were stained for Ia-like antigens, the abundant macrophages in the lamina propria stained very strongly for Ia-like antigens (Fig. 4) and resembled the light microscopic appearance of Ia<sup>+</sup> ID cells observed in tonsils or in the thymic medulla and septae. Furthermore, the intra-epithelial lymphocytes in human gut have recently been shown to be almost exclusively HuTLA<sup>+</sup> T lymphocytes<sup>21</sup>. In contrast to the T cells in the lamina propria, this intra-epithelial T-cell population consisted mainly of OKT8<sup>+</sup> cells (70–90% OKT8<sup>+</sup> cells within the HuTLA<sup>+</sup> population in the three samples analysed).

The observations outlined above are compatible with the view that subsets of peripheral T lymphocytes develop from immature OKT4<sup>+</sup>, OKT8<sup>+</sup> thymocytes through a series of

**Fig. 4** Interdigitating (ID) cells and macrophages in the human thymus (a), tonsil (b) and gut (c). All three preparations are sections from frozen biopsies stained for human Ia-like (p28, 33) antigen with chicken-anti-Ia-like serum (1:40) followed by sheep anti-chicken Ig-TRITC (1:20). a, Areas of interlobular septae contain ID cells (migrating cells?) which resemble circulating lymph-borne veiled cells<sup>28</sup>. The cells exhibit characteristic strongly Ia<sup>+</sup> 'veils' and 'whiskers'. Similar cells are seen around the cortico-medullary junction within the thymus (see Fig. 1). b, A paracortical area from tonsil. The Ia<sup>+</sup> ID cells again show extensive processes which surround the T lymphocytes (not stained, but see insert in Fig. 2). c, A jejunal villus with epithelium (e) very weakly stained for Ia-like antigen and lamina propria (lp) containing large macrophages with abundant Ia-like antigens. The staining patterns suggest that the expression of Ia-like antigens might be cytoplasmic in many of these cells. ×315.

differentiation steps<sup>6,13</sup>. The preponderance of OKT8<sup>+</sup> T cells in the bone marrow suggests that T cells are normal inhabitants of this tissue with a definite physiological role (suppression of immunoglobulin synthesis?) rather than representing contaminating blood-borne T cells.

Intriguingly, while the OKT8<sup>+</sup> subset shows 'affinity' to the gut epithelium which expresses Ia-like antigens poorly, the lymphoid microenvironments (thymic medulla, paracortex, lamina propria) which contain high proportions of 'inducer' T cells exhibit large numbers of Ia<sup>+</sup> non-lymphoid cells. These stain more brightly for Ia-like antigens than B lymphocytes, dendritic cells in the germinal centres or sinus histiocytes<sup>20</sup>. In the literature these cells are variably referred to as ID cells<sup>15-19,22,23</sup>, cells of the cortico-medullary junction<sup>24</sup> or macrophages of the lamina propria<sup>21,25</sup>. Further immuno-electron microscope studies are needed to determine the ultrastructural characteristics, lineage derivation (from marrow precursors? see ref. 26) and cytoplasmic Ia-content (secretion or shedding of Ia?) of this apparently migratory Ia<sup>+</sup> population. It is already known that at least a proportion of ID cells contain Birbeck granules and are related to skin Langerhans cells<sup>23,27</sup> and circulating 'veiled' cells in the lymph<sup>27,28</sup>. These cells all express large amounts of Ia-like antigens<sup>28-30</sup>. The full characterization of this strongly Ia<sup>+</sup> ancillary system for 'inducer' T lymphocytes throughout the body is important since Langerhans cells have already been shown to play a part in transporting foreign antigens from skin to the regional lymph nodes and to 'present' these antigens to T cells<sup>28,29,31</sup>. A similar role could be postulated for the lamina propria macrophages, the 'Cinderella' cells of the gastrointestinal system<sup>25</sup>.

It is also known that 'inducer' T cells see foreign antigens in the context of Ia antigen (in the mouse)<sup>32</sup> or Ia-like HLA-DR antigens (in man)<sup>33</sup> according to the previous thymic education of these cells<sup>32</sup>. In both species, thymic cortical epithelial cells as well as medullary ID cells express large quantities of Ia or Ia-like antigens<sup>11,34</sup>. The close anatomical relation of 'inducer' T cells and Ia<sup>+</sup> cells in the tonsil and gut further suggests that this physiological control of T-cell recognition is maintained in the peripheral lymphoid tissues.

The use of well characterized monoclonal antibodies to T-cell subsets in studies of both cell suspensions and tissue sections of biopsies taken from patients with viral infections, immunoregulatory ('autoimmune') disorders and graft-versus-host disease may well contribute to the understanding of virus control and disease development<sup>7,8,35</sup>.

We thank Dr F. J. Bollum for anti-TdT antibody and Professor S. F. Schlossman for a sample of anti-TH<sub>2</sub> antiserum. Human thymus and bone marrow samples were provided by Mrs L. Layward and Dr N. Rapson of the Institute of Child Health and Dr H. G. Prentice of the Royal Free Hospital, London. Gut biopsies were obtained in collaboration with Dr D. Jewell, Royal Free Hospital, London. W.S.S. was supported by the Coppleson Postgraduate Medical Foundation.

## Different postsynaptic events in two types of retinal bipolar cell

Jonathan F. Ashmore & David R. Copenhagen

Departments of Ophthalmology and Physiology, University of California, San Francisco, California 94143

The first synapse in the vertebrate visual system is made between the photoreceptors and the bipolar cells. Bipolar cells fall into two distinct classes according to whether the cell hyperpolarizes or depolarizes to small centred spots of light. Most evidence indicates that the light-induced hyperpolarization of the photoreceptors suppresses transmitter release from the synaptic terminals<sup>1-3</sup>, and it is probable that the differences between the two bipolar cell classes results from the different actions of the photoreceptor transmitter<sup>4</sup>. In analysing the membrane potential fluctuations in both types of bipolar cell we find that the voltage noise spectra differ. It is to be expected that postsynaptic noise would be composed of the sum of noise generated in and transmitted from the cones<sup>5,6</sup> and the noise arising from the statistical nature of synaptic transmission. We report here evidence for two such components in the voltage noise spectra recorded from each type of bipolar cell. The differences in the frequency distribution of the presumed transmitter-related components indicates that the transmitter generates events of longer duration in the depolarizing bipolar cells.

Eyecup preparations from the snapping turtle (*Chelydra serpentina*) were mounted in a chamber through which moist oxygen flowed and such that small spots of light could be focused on the impaled cell<sup>7</sup>. Bipolar cells were recorded at depths of 120-180  $\mu$ m distal to the vitreal surface of the retina. A sample of studied cells were stained with either Procion yellow or Lucifer<sup>8</sup> and all positively identified as bipolar cells. Although a rod input may be demonstrated in certain cells, we have investigated the red cone input only<sup>9</sup>. The stimulus was a 100  $\mu$ m spot of 650 nm light centred on the impaled cell.

In hyperpolarizing bipolar cells, steps of light reduced potential fluctuations<sup>10</sup> (Fig. 1a). The total noise variance decreased 27-fold for this cell, from 1.1 mV<sup>2</sup> in the dark to 0.04 mV<sup>2</sup> in bright light. This reduction appears to reflect primarily the cutoff of the cone transmitter and cannot be attributed to a potential-dependent membrane resistance decrease since we find that the hyperpolarization is associated with an increase in cell input resistance. In addition, we find that hyperpolarization of the cell to the light evoked levels by extrinsic current does not suppress the noise in the dark.

The potential fluctuations were Fourier analysed to obtain a difference spectrum between the spectra in the dark and in the light. The difference spectra were found to have the same form at all light levels, the effects of illumination being to rescale their amplitude. A difference spectrum between dark and bright light

**Fig. 1** Voltage noise in hyperpolarizing bipolar cells. *a*, Response of a cell to a 100- $\mu\text{m}$  spot of 650-nm light with an intensity of  $9.85 \times 10^4$  photons  $\mu\text{m}^{-2} \text{s}^{-1}$ . Maximum response to flashes; 21 mV. *b*, Difference spectrum (dark – bright) of the voltage noise for the hyperpolarizing bipolar cell (●) and a cone (○). The cone spectrum has been multiplied by a factor of 26 for normalization. The records were filtered at 100 Hz, and sampled at 400 Hz (bipolar cells) or 500 Hz (cones) for processing using a 1,024-point FFT program. The spectrum is frequency smoothed. The extracellular electrode noise variance was less than 0.01  $\text{mV}^2$ . The continuous curve *S*, is the sum of the two functions shown as dotted curves<sup>10</sup>. *S<sub>H</sub>* is proportional to the modulus squared of the Fourier transform of equation (1) with  $T = 5.9$  ms; *S<sub>L</sub>* is the product of *S<sub>H</sub>* and two lorentzian functions with time constants 54.9, 9.2 ms required to fit the cone spectrum<sup>6</sup>. The ratio of the variances associated with the components *S<sub>L</sub>*:*S<sub>H</sub>* is, by numerical computation, 1.57:1. *c*, Signal-averaged and normalized responses of a cone and hyperpolarizing bipolar cell, both cells within their linear ranges. The dotted lines are *C*, seven-stage low-pass filter model with time constant per stage = 20 ms (ref. 5), and *H*, the function after passing through a filter given by equation (1) with  $T = 5.9$  ms. The difference in times to peak is 13 ms.

is shown in Fig. 1*b* and falls off asymptotically as  $1/f^4$  with more power at high frequencies than found in cones<sup>6</sup>. In some cells there was a very pronounced inflection at around 10 Hz and, unlike the voltage noise spectrum recorded in cones, the spectrum could not be fitted by the simple product of lorentzian functions<sup>6</sup>. Instead, the following model leads to a fit of the noise difference spectrum as a sum of two components, *S<sub>L</sub>* and *S<sub>H</sub>*. The release of transmitter from the cones and its postsynaptic action may be considered to be a shot process, and will result post-synaptically in a noise spectrum *S<sub>H</sub>*(*f*) (ref. 11). If the rate of transmitter release were a linear function of the presynaptic cone membrane potential, with fluctuations described by a spectrum *S<sub>C</sub>*(*f*) (ref. 6), it can be shown that there will be an additional term *S<sub>L</sub>*(*f*) = constant  $\times S_C(f) \times S_H(f)$  present in the spectrum of the postsynaptic fluctuations (compare ref. 11, equation 2.6–11). The term *S<sub>L</sub>*(*f*) will have power restricted to lower frequencies than *S<sub>H</sub>*(*f*) and arises because the synapse acts to filter the noise transmitted from the cones.

The simplest unitary event sufficient to describe the component *S<sub>H</sub>* has the form  $\alpha(t)$  given by

$$\alpha(t) = (\alpha/T) \exp(-t/T + 1) \quad (1)$$

where  $\alpha$  is the amplitude, *T* the time to peak, is 5.9 ms and the event halfwidth is 14.5 ms. The spectrum associated with the event given by equation (1) is then

$$S_H(f) = \frac{S_H(0)}{(1 + 4\pi^2 T^2 f^2)^2} \quad (2)$$

$\alpha(t)$  is formally equivalent to the impulse response of a two-stage low pass filter<sup>12</sup>, where both stages have the time constant *T*. One stage of this filter most probably represents the membrane time constant,  $\tau$ . In a sample of nine cells we found  $\tau = 9.2 \pm 5.0$  ms (mean  $\pm$  s.d.). Hence, the likely duration of transmitter action corresponding to the second filter stage, would be no greater than 6 ms.

Equation (1) also describes the effective filter representing the cone–bipolar synapse. Figure 1*c* shows that the response in the hyperpolarizing bipolar cell can be predicted by simply passing the cone response through this filter. The early phase of the bipolar response is predicted well, corresponding to frequencies in the spectrum above 1 Hz. The overshoot in the repolarization of the bipolar cell response can be ascribed to an additional differentiation occurring for frequencies below about 1 Hz, which is not included in this model. Such a differentiating stage has also been postulated in the retinal signal pathway from the photoreceptors to account for some of the properties of ganglion cell firing patterns in the turtle retina<sup>13</sup>.

A similar analysis of the fluctuations may be made for depolarizing bipolar cells. Dim lights usually, but not always, produced an increase in intracellularly recorded voltage noise. In the cell shown in Fig. 2, the noise variance increased from 0.055  $\text{mV}^2$  to 0.154  $\text{mV}^2$  for a 1.5-mV depolarization, with an accompanying cell input resistance decrease<sup>1</sup>. Further increase in the light intensity produced a noise suppression to a level close to that in the dark. The initial increase in noise might be expected if the postsynaptic action of transmitter were to block ionic channels<sup>1,4</sup> and if a majority of the channels were blocked in the dark<sup>10</sup>.

Figure 2*b* illustrates the difference spectrum of voltage noise between dim light and the dark. Although, in contrast to the hyperpolarizing bipolar cells, there was no clearly indicated inflection point in the noise spectra, it was found that the noise had a narrower bandwidth than for hyperpolarizing bipolar cells or cones. A decomposition of the voltage noise spectrum was obtained by considering the synaptic filtering required to produce the delay in the flash response (Fig. 2*c*). The observed delay can be obtained using equation (1) with  $T = 21$  ms as the synaptic filter, in which case the associated unitary voltage event would have a half duration of 49 ms. For the input time constant

of depolarizing bipolar cells, it was found that  $\tau = 7.2 \pm 3.5$  ms ( $n = 5$ ). The membrane time constant,  $S_H(f)$ , in the spectral decomposition (Fig. 2b) can be consistently interpreted as accounting for one stage of the filter if the duration of transmitter-activated conductance change is not less than 21 ms, corresponding to the other stage of the synaptic filter. Conversely, an upper bound for the duration of the event in the depolarizing bipolar cell can be obtained if the spectrum is fitted

**Fig. 2** Voltage noise in depolarizing bipolar cells. *a*, Response of a cell to a 100  $\mu\text{m}$  spot with an intensity of 1,380 photons  $\mu\text{m}^{-2} \text{s}^{-1}$ . Maximum response to flashes, 11 mV. *b*, Difference spectrum (dim - dark) of the voltage noise for the bipolar cell (●). Cone spectrum (○) as before, multiplied by 4.8 for normalization. The dotted curve  $S_H$  is obtained from equation (2) with  $T = 21$  ms.  $S_L$  is constructed as in the text. The ratio of the variances associated with the components  $S_L : S_H$  is computed to be 2.66 : 1 to provide the best fit to the data. *c*, Normalized linear range responses to a flash of light in a cone (inverted) and the bipolar cell with computed cone *C* and bipolar cell *D* responses. The difference in time to peak between the responses is 41 ms. The hyperpolarization during recovery of the bipolar cell indicates differentiation at this stage of synaptic processing.

by a single component of the form of equation (2), which would lead to an event with a half duration of 82 ms. Thus it appears by either analysis that the transmitter event in the hyperpolarizing bipolar cell may be much shorter than in the depolarizing bipolar cell.

The differences in the temporal properties of the synapses between the two cell types may indicate that each is specialized for a different role. By recording ganglion cell spikes elicited by current injection into cones differences in the latency between the on- and off-pathways to the ganglion cells have been described<sup>13</sup>. It is possible that this functional difference may be established at the level of the outer plexiform layer. The wider passband of the cone-hyperpolarizing bipolar cell synapse may be appropriate for signals in the photopic range when the response of the photoreceptors themselves speed up<sup>12</sup>.

However the narrower range of frequencies passed by the depolarizing bipolar cell synapse is matched closely to the temporal characteristics of the cell's response to a flash of light. Such an arrangement would be advantageous in the detection of light in the mesopic range.

We thank Drs Juan Korenbrot and Julie Schnapf for helpful comments on the manuscript. This work was supported by NIH grant EY-01869.

## Somatostatin selectively inhibits noradrenaline release from hypothalamic neurones

M. Göthert

Institute of Pharmacology, University of Essen, Hufelandstr. 55, D-4300 Essen 1, FRG

Somatostatin is a hypothalamic peptide hormone which inhibits growth hormone release from the anterior pituitary<sup>1</sup>. However, biochemical and morphological investigations have revealed that somatostatin is located not only in the hypothalamus but also in other brain areas (for example the cerebral cortex) where it occurs and in nerve cell bodies and fibres<sup>2-5</sup> from which it can be released in a  $\text{Ca}^{2+}$ -dependent manner<sup>6</sup>. It has therefore been suggested that the neuropeptide may have functions in the central nervous system other than its effect on growth hormone release<sup>7</sup>; one possible action is that of a neuromodulator<sup>4,6</sup>. Therefore, hypothalamic and cerebral cortical slices of the rat were used to examine whether somatostatin modifies the electrically or  $\text{CaCl}_2$ -evoked release of tritiated monoamines from monoaminergic neurones. It is reported here that somatostatin inhibits  $^3\text{H}$ -noradrenaline release from the hypothalamus (but not from the cerebral cortex) but does not affect the release of  $^3\text{H}$ -dopamine and  $^3\text{H}$ -serotonin.

Slices of hypothalamus or occipital cortex (0.3 mm thick, diameters 2.0 and 3.0 mm, respectively) from male Wistar rats (200-300 g) were incubated for 60 min in physiological salt solution (of composition described in Fig. 1 legend) containing one of the following tritiated monoamines at a concentration of

0.1  $\mu\text{M}$ :  $^3\text{H}$ -(-)noradrenaline (21.3–25.4 Ci  $\text{mmol}^{-1}$ ),  $^3\text{H}$ -dopamine (32.6 Ci  $\text{mmol}^{-1}$ ) or  $^3\text{H}$ -serotonin (25 Ci  $\text{mmol}^{-1}$ ). In these conditions the tritiated monoamines are selectively taken up into noradrenergic, dopaminergic and serotonergic neurones of the slices, respectively.<sup>8–10</sup>

After incubation, the slices were superfused with either physiological salt solution or  $\text{Ca}^{2+}$ -free solution containing 25 mM  $\text{K}^+$  (isomolar replacement of  $\text{NaCl}$  by  $\text{KCl}$ ). Each slice was stimulated 40 and 90 min after the onset of superfusion ( $S_1$ ,  $S_2$ , duration 2 or 6 min; Fig. 1). Slices superfused with physiological salt solution were stimulated by an electrical field (13 mA; rectangular pulses) generated between two platinum ring electrodes, and slices superfused with  $\text{Ca}^{2+}$ -free,  $\text{K}^+$ -rich solution were stimulated by introduction of 0.65 mM  $\text{CaCl}_2$ . In the experiments with somatostatin, the peptide was present from 25 min before  $S_2$  until the end of the experiments. The radioactivity in the superfusates and slices was determined by liquid scintillation counting. All details of the methods used and the calculation of stimulated  $^3\text{H}$  overflow above basal efflux have been described previously.<sup>11,12</sup> The electrically or  $\text{CaCl}_2$ -evoked  $^3\text{H}$  overflow (for absolute values, see Table 1) from slices preincubated with a  $^3\text{H}$ -labelled monoamine mainly consists of the respective, nonmetabolized  $^3\text{H}$ -monoamine<sup>11–14</sup> which is released from the corresponding neurones.

Somatostatin at up to 1  $\mu\text{M}$  did not affect the basal efflux of  $^3\text{H}$ -noradrenaline,  $^3\text{H}$ -dopamine or  $^3\text{H}$ -serotonin. However, at

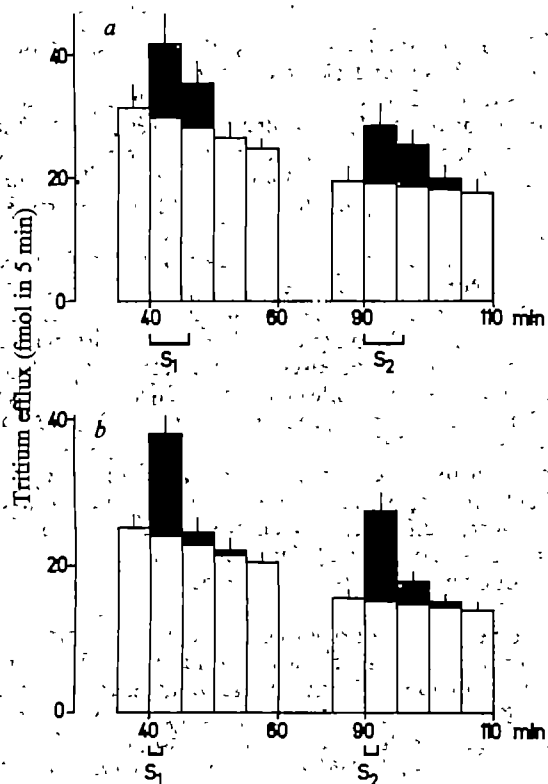

**Table 1** Stimulation-evoked tritium overflow above basal efflux from superfused rat brain slices preincubated with tritiated monoamines

| Slices preincubated with $^3\text{H}$ -noradrenaline |                  |                      |

All values represent tritium overflow evoked by the second period of stimulation ( $S_2$ ; 90 min after onset of superfusion; control experiments; means  $\pm$  s.e.m.;  $n = 5-7$ ).

\* Slices were stimulated either electrically (1 or 3 Hz, 360 pulses, 13 mA; superfusion with physiological salt solution) or by introduction of 0.65 mM  $\text{CaCl}_2$  for 6 min after superfusion with  $\text{Ca}^{2+}$ -free,  $\text{K}^+$ -rich solution containing 1  $\mu\text{M}$  tetrodotoxin.

† % of tissue tritium at the onset of the respective stimulation period.

**Fig. 1** Tritium efflux from rat hypothalamic slices preincubated with  $^3\text{H}$ -noradrenaline (means  $\pm$  s.e.m.). The slices were superfused with physiological salt solution of the following composition (mM):  $\text{NaCl}$  118,  $\text{KCl}$  4.8,  $\text{CaCl}_2$  1.3,  $\text{KH}_2\text{PO}_4$  1.2,  $\text{MgSO}_4$  1.2,  $\text{NaHCO}_3$  25, ascorbic acid 0.06, disodium-EDTA 0.03, glucose 10 (aeration with 95%  $\text{O}_2$  and 5%  $\text{CO}_2$ ; 37  $^{\circ}\text{C}$ ). The superfusate was collected in 5-min samples, and the radioactivity was measured by liquid scintillation counting. The slices were stimulated electrically with 360 pulses at frequencies of either 1 Hz (a;  $n = 7$ ) or 3 Hz (b;  $n = 7$ ). Two periods of stimulation were applied, 40 ( $S_1$ ) and 90 min ( $S_2$ ) after the onset of superfusion (duration of stimulation indicated by the horizontal bars). The stimulation-evoked  $^3\text{H}$  overflow above basal efflux is indicated by the shaded areas of the columns.

concentrations of 0.32 and 1.0  $\mu\text{M}$  the peptide inhibited electrically (3 Hz, 2 min) induced  $^3\text{H}$ -noradrenaline overflow from hypothalamic slices (Table 2). This inhibition was of a similar magnitude when the slices were stimulated at a frequency of 1 Hz for 6 min. Thus, in seven controls the ratio of  $^3\text{H}$  overflow evoked by  $S_2$  to that evoked by  $S_1$  ( $S_2/S_1$ ) was  $1.14 \pm 0.12$  (means  $\pm$  s.e.m.), whereas it was  $0.84 \pm 0.04$  ( $P < 0.05$ , Student's  $t$ -test;  $n = 7$ ) when 0.32  $\mu\text{M}$  somatostatin was present from 25 min before  $S_2$ . In contrast, the electrically (3 Hz) induced overflow of  $^3\text{H}$ -dopamine or  $^3\text{H}$ -serotonin from hypothalamic slices was not altered by somatostatin at up to 1  $\mu\text{M}$  (Table 2). Interestingly, the impulse-evoked  $^3\text{H}$ -noradrenaline overflow from cortical slices was also not inhibited by the peptide, although the experimental conditions were identical to those used in hypothalamic slices (see Fig. 1 legend; frequency of stimulation 3 Hz). Thus the ratio  $S_2/S_1$  was  $1.04 \pm 0.04$  ( $n = 5$ ) in control conditions, and  $0.96 \pm 0.06$  (no significant difference) in six experiments with 0.32  $\mu\text{M}$  somatostatin.

Because electrically evoked  $^3\text{H}$ -noradrenaline release from brain slices is  $\text{Ca}^{2+}$  dependent<sup>12</sup>, the inhibitory effect of somatostatin on impulse-evoked release from hypothalamic slices may be due to a decrease in the availability of  $\text{Ca}^{2+}$  ions for stimulus-release coupling. This hypothesis was tested by investigating the effect of somatostatin on  $^3\text{H}$ -noradrenaline

**Table 2** Effect of somatostatin on electrically evoked tritium overflow from superfused slices of rat hypothalamus preincubated with  $^3\text{H}$ -monoamines

| Somatostatin<br>( $\mu\text{M}$ ) | Tritium overflow ( $S_2/S_1$ )<br>after preincubation with |                        |                         |
|-----------------------------------|--|------------------------|-------------------------|
|                                   | $^3\text{H}$ -noradrenaline                                | $^3\text{H}$ -dopamine | $^3\text{H}$ -serotonin |
| 0                                 | 1.12 $\pm$ 0.07  | 1.05 $\pm$ 0.09        | 1.00 $\pm$ 0.04         |
| 0.1                               | 0.96 $\pm$ 0.03  | —                      | —                       |
| 0.32                              | 0.77 $\pm$ 0.03*   | 0.97 $\pm$ 0.05        | —                       |
| 1.0                               | 0.73 $\pm$ 0.08*   | 1.08 $\pm$ 0.13        | 0.99 $\pm$ 0.05         |

The slices were superfused with physiological salt solution. Tritium overflow was stimulated twice, after 40 ( $S_1$ ) and 90 min ( $S_2$ ) of superfusion (3 Hz, 2 min), and the ratio of the overflow (above basal  $^3\text{H}$  efflux; expressed as % of tissue tritium at the onset of stimulation) evoked by  $S_2$  and that evoked by  $S_1$  was determined ( $S_2/S_1$ ; means  $\pm$  s.e.m.;  $n = 5-7$ ). Somatostatin was present from 25 min before  $S_2$  until the end of the experiments.

\*  $P < 0.005$  (compared with the experiments without somatostatin).

release from hypothalamic slices evoked by the introduction of  $0.65 \text{ mM Ca}^{2+}$  after superfusion with  $\text{Ca}^{2+}$ -free solution containing  $25 \text{ mM K}^+$  and  $1 \mu\text{M}$  tetrodotoxin throughout the experiments. This  $\text{Ca}^{2+}$ -induced  $^3\text{H}$  overflow is due to  $\text{Ca}^{2+}$  influx into the noradrenergic fibres via the potential-sensitive permeability channel of the cell membrane<sup>11</sup>. In five control experiments, the ratio  $S_2/S_1$  was  $1.18 \pm 0.18$ , decreasing to  $0.63 \pm 0.14$  ( $n = 5$ ;  $P < 0.05$ ) when  $0.32 \mu\text{M}$  somatostatin was present from 25 min before  $S_2$  until the end of the experiments.

In conclusion, the present investigation revealed that somatostatin selectively inhibits the stimulated release of  $^3\text{H}$ -noradrenaline from noradrenergic nerve fibres of the hypothalamus, leaving that from cerebral cortex and also the release of  $^3\text{H}$ -dopamine and  $^3\text{H}$ -serotonin from hypothalamus unaffected. The terminal fibres of central noradrenergic neurones are known to possess various presynaptic

receptors<sup>12,15,16</sup> which modulate release by modifying  $\text{Ca}^{2+}$  influx via the potential-sensitive permeability channel<sup>17</sup>. Therefore, it is possible that presynaptic somatostatin receptors exist on the noradrenergic fibres of the hypothalamus. The presynaptic site of action seems likely, because the effect of somatostatin was also observed in the presence of tetrodotoxin (which inhibits the propagation of action potentials by decreasing the  $\text{Na}^+$  permeability of the cell membrane), thus excluding the possibility that interneurons are involved in this effect. Our experiments in which  $\text{Ca}^{2+}$  ions were used for stimulation revealed that the inhibition is probably due to a decrease in  $\text{Ca}^{2+}$  influx into the terminal noradrenergic fibres.

I thank Miss B. Giesen and Miss G. Werthmann for technical assistance and Serono for the gift of cyclic somatostatin. This study was supported by the Deutsche Forschungsgemeinschaft.

§ The Roche Institute, Nutley, New Jersey

**The enkephalins Met-enkephalin and Leu-enkephalin were first isolated from porcine brain by Hughes and co-workers<sup>1</sup>. We have recently isolated from bovine adrenals another enkephalin with the structure Tyr-Gly-Gly-Phe-Met-Arg-Phe, or Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> (ref. 2). We report here that this new heptapeptide is found in human, rat and bovine striatum in concentrations comparable with or greater than that of Leu-enkephalin. This molecule should not be considered as a mere precursor of Met-enkephalin. A pharmacological study indicates that this naturally occurring enkephalin has similar properties to the two enkephalins characterized earlier.**

To demonstrate the presence of this molecule in brain extracts, we used an HPLC system coupled with a new radioimmunoassay (RIA) which used an antiserum whose specificity is directed against the N-terminus (Tyr<sup>1</sup>-) of the enkephalins. This antiserum reacts as well with Leu-enkephalin as it does with Met-enkephalin. Molecules with a C-terminus deletion (des-Met, Met-enkephalin) or a C-terminus addition (Met-enkephalin-Arg<sup>6</sup>, Met-enkephalin-Lys<sup>6</sup> and Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup>) also react strongly with this serum (Fig. 1).

HPLC enables all the known enkephalin congeners to be separated in a single run. The system described in Table 1 uses an Ultrasphere octyl column eluted by a gradient of propanol. To detect minute amounts of enkephalins in the eluate we used the RIA described above, which has a sensitivity of 20 pg per tube. The broad specificity of this antiserum is an advantage in that all the characterized enkephalins can be quantified by the same assay.

Table 1 shows that in the striatum and in isolated chromaffin cells Met-enkephalin and Leu-enkephalin were not the only compounds detected by our RIA. We found compounds corresponding to oxidized Met-enkephalin, Met-enkephalin-Arg<sup>6</sup> and Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup>. Trace amounts of Leu-enkephalin-Arg<sup>6</sup> (retention time 24 min) and of oxidized Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> (retention time 72 min) were also detected.

In all the species examined, Met-enkephalin was always the predominant compound. This contrasts with a report from Simantov and Snyder, who have claimed that in cattle, Leu-enkephalin is the predominant peptide<sup>3</sup>. To ensure that our relatively lower values for Leu-enkephalin were not due to our RIA procedure, we have confirmed these values with two other assays, a RIA specific for the C-terminus of Leu-enkephalin and a radioreceptor assay<sup>4,5</sup>.

Compared with values for Met-enkephalin, the amount of Met-enkephalin-Arg<sup>6</sup> was important in man and rat but not in cattle, a species difference which we cannot explain. This compound has also been isolated from porcine hypothalamus by another group who have called the molecule a pro-Met-enkephalin<sup>6</sup>.

The relative amount of oxidized Met-enkephalin was quite high in human and bovine extracts but not in the rat extracts. The possibility that the oxidation of Met-enkephalin had occurred after death or before or during the preparation of the extracts with 10% trichloroacetic acid, cannot be ruled out.

Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> was found in high amounts in the three species examined. In rat and human striatal extracts the concentration was higher than that of Leu-enkephalin. This is seen particularly in the human extract, which contained four times more Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> than Leu-enkephalin. This very high ratio of Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> to Leu-enkephalin was also found in chromaffin cells isolated from the bovine adrenal medulla.

The presence of this compound in high amounts in all species examined raises some questions about its role in the brain. We have recently reported that this molecule has analgesic activity when administered intraventricularly to mice. On a molar basis, Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup>, with an ED<sub>50</sub> of 38.5 nmol per mouse, was 8 times more potent than Met-enkephalin in the tail flick test but 63 times less potent than morphine<sup>7</sup>. However, it

Striata from 10 rats (Sprague-Dawley, 200 g) were dissected out and frozen immediately after decapitation. Striata from three bovine brains were obtained in the 3 h following death. The human tissue was obtained at autopsy, 8 h after death, from a 68-yr old woman who died from a pulmonary embolism. In this case only the two putamens were used. Isolated bovine chromaffin cells were prepared as described by Livett *et al.*<sup>10</sup>. In all cases the pooled tissues were incubated for 10 min at 95 °C in 10 vol of 1 M acetic acid before homogenization as described in ref. 11. The supernatant (3,000g × 30 min) was precipitated with 10% final trichloroacetic acid, the precipitate was discarded and the solution extracted three times with an equal volume of diethyl ether. The solution was adjusted to pH 4 with pyridine and applied to an Ultrasphere octyl column (5 µm, 4.6 × 250 mm). The column was eluted by a linear gradient of 1-propanol (from 7 to 14% in 100 min) in 0.5 M formic acid/0.4 M pyridine as described elsewhere<sup>12</sup>. Flow rate was 30 ml h<sup>-1</sup>. Fractions of 0.75 ml were collected. After evaporation, the residue was resuspended in the RIA buffer and assayed as described in Fig. 1 legend. Positive fractions were reassayed at two or three appropriate dilutions.

**Table 2** Inhibition of binding to rat brain membranes

| Peptide   | <sup>3</sup> H-etorphine IC <sub>50</sub> (nM) | <sup>3</sup> H-(D-Ala <sup>2</sup> )-Leu-enkephalinamide IC <sub>50</sub> (nM) |
|---|--|--|
| Met-enkephalin                                    | 25 ± 6 (3)                                     | 17 ± 2 (3)   |
| Met-enkephalin-Arg <sup>6</sup> -Phe <sup>7</sup> | 35 ± 2 (3)                                     | 36 ± 8 (3)   |
| Leu-enkephalin                                    | 51 ± 10 (3)                                    | 35 ± 3 (3)   |

Rat brain minus the cerebellum was homogenized with a Teflon-glass homogenizer (1,500 r.p.m., 5 strokes) in 10 ml of 0.05 M Tris-HCl buffer pH 7.4, centrifuged at 49,000g for 10 min, the pellet rehomogenized in 10 ml of Tris buffer and re-centrifuged. The pellet was resuspended in Tris buffer to obtain a final concentration of 1 mg per ml. The suspension (0.8 ml) was incubated for 150 min at 0 °C in the presence of either <sup>3</sup>H-etorphine (1 nM) or <sup>3</sup>H-(D-Ala<sup>2</sup>)-Leu-enkephalinamide (3.5 nM) and unlabelled peptides. Nonspecific binding was determined with 1 µM levorphanol for <sup>3</sup>H-etorphine and 1 µM (D-Ala<sup>2</sup>)-Leu-enkephalinamide for <sup>3</sup>H-(D-Ala<sup>2</sup>)-Leu-enkephalinamide as described in ref. 13. The values are the means ± s.e.m.; the number of observations is given in parentheses.

Assays were performed as described in ref. 13. The values are means ± s.e.m.; the number of observations is given in parentheses.

was possible that the analgesic effect of the heptapeptide was due to its biotransformation. Indeed, *in vitro* Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> can be converted to Met-enkephalin by a sequential digestion with trypsin and carboxypeptidase B. To eliminate this possibility we have characterized the new compound in conditions where biotransformation should not occur.

To minimize any enzymatic transformation in our radioligand displacement assay, we have used washed rat brain membranes and incubated them at 0 °C. As Table 2 shows, Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> was as potent as Leu-enkephalin in displacing <sup>3</sup>H-etorphine or <sup>3</sup>H-(D-Ala<sup>2</sup>)-Leu-enkephalinamide from the purified rat brain membranes. The heptapeptide was slightly less active than Met-enkephalin.

We further characterized the new compound on two classical preparations for opiates, the guinea pig ileum and the mouse vas deferens<sup>8</sup>. On the guinea pig ileum, Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> inhibited the electrically induced twitch with an IC<sub>50</sub> of 322 nM.

**Fig. 1** Cross-reactivities of the N-terminus Met-enkephalin (E) antiserum. A rabbit was injected intradermally at multiple sites with 2 mg of the immunogen emulsified in Freund's complete adjuvant. A month after the first injection it was boosted and serum collected 10 days later. The immunogen was prepared as follows: 40 mg of crystalline bovine serum albumin and 76 mg of 1-ethyl-3-(3-dimethyl-aminopropyl)-carbodiimide HCl were dissolved in 2 ml water. The pH was adjusted to 3. After 4 min in an ice bath, 57 mg of Boc-Met-enkephalin-NH-(CH<sub>2</sub>)<sub>2</sub>-NH<sub>2</sub> pre-dissolved in 4 ml was added. After 1 h the resulting milky solution was dialysed and lyophilized. The powder was treated with trifluoroacetic acid for 15 min. The trifluoroacetic acid was pumped off under high vacuum, and the resulting brown gelatinous precipitate resuspended in 30% acetic acid/water and dialysed against water. The RIAs were carried out at a final serum dilution of 1/600. The maximum binding was 21%. Serum, trace and standard were incubated for 48 h at 4 °C in a final volume of 300 µl of a 10 mM sodium phosphate buffer pH 7.5, 145 mM NaCl, supplemented with thimerosal 0.01%, gelatine 0.1% and crystalline bovine serum albumin 0.01%. Trace was monoiodo-(<sup>125</sup>I)-Leu-enkephalin prepared as described in ref. 4 and purified by HPLC. Similar results were obtained with monoiodo-(<sup>125</sup>I)-Met-enkephalin. γ-Globulins were precipitated with 0.5 ml of a preparation of formalin-treated *Staphylococcus aureus* after an incubation of 10 min at room temperature. This preparation (Ig Sorb, Enzyme Center, Boston) was diluted 20 times with phosphated-buffered saline before use. After centrifugation (2,000g × 10 min) the supernatant was discarded and the pellet counted. Results are in % of B/B<sub>0</sub>. Expressed in molar ratio, the cross-reactivities relative to Met-enkephalin were 100% with sulphoxide Met-enkephalin and Leu-enkephalin, 42% with Met-enkephalin-Lys<sup>6</sup>, 30% with Tyr-Gly-Gly-Phe, 23% with Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup>, 19% with Met-enkephalin-Arg<sup>6</sup>, 1.5% with γ-endorphin, 0.75% with α-endorphin, 0.25% with β-endorphin and 0.20% with δ-endorphin. Parallelism was found for all these compounds except for Met-enkephalin-Lys<sup>6</sup>. No cross-reactivity was found with morphine, tyrosine, des-Tyr<sup>1</sup>-β-endorphin or β-lipotropin tested at concentration up to 1 µg per tube.

On this preparation Met-enkephalin was slightly more active and Leu-enkephalin 50% less active. These effects were almost completely antagonized by naloxone ( $5 \times 10^{-7}$  M).

Kosterlitz and co-workers have demonstrated the existence of at least two types of opiate receptor— $\mu$  and  $\delta$  in the guinea pig ileum and mouse vas deferens, respectively<sup>8,9</sup>. Leu-enkephalin was considered to be a  $\delta$  agonist, being much more potent on the vas deferens than on the guinea pig ileum. On the other hand, morphine was considered to be a  $\mu$  agonist, being much more potent on the guinea pig ileum than in the vas deferens. In our preparations the ratios of the activity on the guinea pig ileum to that on the mouse vas deferens were 0.19 for morphine and 14.3 for Leu-enkephalin (Table 3). Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> had a ratio of 4.81 against 3.22 for Met-enkephalin. Kosterlitz *et al.*<sup>9</sup> recently showed that compounds with high ratios interacted mainly with  $\delta$  receptors. Thus, it seems reasonable to consider that the new heptapeptide binds preferentially to the  $\delta$  receptor rather than to the  $\mu$  receptor.

Met-, Leu-enkephalin and  $\beta$ -endorphin have previously been considered as the main endogenous opioid ligands in the brain. Our report shows that Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup> is another important endogenous opioid peptide. The crucial problem now is to determine by immunocytochemistry whether or not this compound is present in neurones containing Met- or Leu-enkephalin.

We thank Drs J. Pablo Huidobro-Toro, Sadao Kimura, Randolph Lewis, Stanley Stein, Alvin Stern and Jean-Jacques Vanderhaeghen for their help. J.R. is Chargé de Recherche INSERM (France).

**Note added in proof:** The analgesic properties of the heptapeptide were markedly enhanced by preparing an analogue more resistant to degradation by peptidases. This compound (D-Ala<sup>2</sup>)-Met-enkephalin-Arg<sup>6</sup>-Phe<sup>7</sup>-NH<sub>2</sub> was, on a molar basis, 130 times more potent than the natural compound and twice as potent than morphine when administered intraventricularly to mice.

## Development of virus non-producer lymphosarcomas in pet cats exposed to FeLV

Naturally occurring oncoviruses of several species<sup>1–6</sup> are transmitted contagiously and cause lymphosarcoma (LSA) or leukaemia in their hosts<sup>7</sup>. All naturally occurring oncoviruses replicate *in vivo* in the tumours they induce or, as with bovine leukaemia virus, can be isolated from tumour cells grown in short-term cell culture<sup>7,8</sup>. However, we have shown that feline leukaemia virus (FeLV) is not present in a significant minority of pet cats that develop LSA<sup>9–11</sup>. Unlike experimentally induced virus-negative leukaemias and sarcomas of other species, LSA cells from FeLV-negative LSA cats lack any FeLV proteins, including p15 or p12, and complete functional copies of FeLV provirus and thus do not produce FeLV when grown in cell culture<sup>9–11</sup>. Thus, except for FeLV, the naturally occurring animal leukaemogenic oncoviruses seem to induce only virus-producing lymphoid tumours. Our earlier findings prompted a study to determine the frequency of occurrence of FeLV non-producer (NP) LSA in pet cats and whether NP LSAs develop in cats exposed to FeLV. We report here epidemiological data which indicate that development of NP LSAs in pet cats is associated with exposure to FeLV and suggest that FeLV may be the aetiological agent for FeLV NP feline LSAs. Thus, feline NP LSAs may be suitable for studying the potential viral aetiology and mechanism of leukaemogenesis of human lymphoid tumours in which no oncoviruses have, as yet, been proved to cause the disease.

The FeLV status of most cats with LSA was determined by the immunofluorescent antibody (IFA) test for FeLV performed on

peripheral blood leukocytes using a multivalent rabbit anti-FeLV serum which detects FeLV gp70, p30, p15, and p12 (ref. 17); but an immunodiffusion test<sup>2</sup>, tissue culture isolation<sup>9</sup>, and radioimmunoassays (RIAs)<sup>18</sup> were also done to determine the FeLV status of some cats. The presence of RD114 viral proteins was determined by RIAs of LSA cell lysates<sup>19</sup>. In general, the results of the IFA test for FeLV correlated well with all other immunological tests and with tissue culture isolation (Table 1 and refs 9, 11, 13, 17, 19 and 20). We compared the results of the IFA test from 274 cats with our ability to recover infectious FeLV in tissue culture from these cats. We could isolate FeLV from only three of the 153 IFA test-negative cats, a 98% concordance between the two methods of FeLV detection. Conversely, FeLV was isolated from 118 of 121 IFA test-positive cats, a 97.5% concordance. Similar results were obtained when we studied cats with LSA. Of the 57 IFA test-positive LSA cats, 56 (98.3% concordance) were found to have FeLV by tissue culture isolation and of the 33 IFA test-negative LSA cats 31 (93.9% concordance) had no FeLV. These results indicate that detection of FeLV antigens by the IFA test is equivalent to the detection of infectious FeLV. Furthermore, the IFA test can detect even the partial FeLV expression that occurs in FeSV-transformed NP mink cells which do not replicate FeLV or FeSV but which express only FeLV p15 and p12 (ref. 21).

We tested 507 LSA cats for the presence of FeLV and 14 LSA cats for the presence of RD114 viral proteins. We found that 360 of the 507 cats tested (71.0%) had FeLV-positive LSAs and 147 (29.0%) had NP LSAs (Table 2). NP LSAs occurred most frequently in cats with the alimentary form of LSA (Table 2). As reported previously, we found that cats with NP LSA were markedly older than cats which developed FeLV-positive LSAs<sup>14</sup>. The mean age of cats with NP LSAs was 6.7 yr; and the median age was 7 yr. In contrast, the mean age of the cats with FeLV-positive LSA was 2.9 yr; and their median age was only 2 yr. Nine FeLV-positive LSAs were tested by RIA and were found to contain large quantities of FeLV structural proteins (Table 1), whereas nine NP LSAs were found to have no detectable FeLV gp70, p30, p15, or p12. However, as reported previously<sup>14</sup>, both the FeLV-positive and NP LSAs had low levels of RD114 gp70 (21–22 ng per mg protein) and p15 (34–36 ng per mg protein) whereas FeLV-positive and -negative normal lymphoid tissues had no detectable RD114 antigens (Table 1).

**Table 1** Expression of feline leukaemia and RD114 viral antigens and the feline oncornavirus-associated cell membrane antigen (FOCMA) in normal and lymphosarcoma tissues of pet cats

| Total cats           |                             | 1,612       |              |                   |                 |                                 |       |   |

\* The observation periods for both FeLV-unexposed control cats and FeLV-infected and -uninfected exposed cats were determined in the following ways. For the unexposed FeLV-uninfected control cats the observation period was the age of the cat on the date of its last FeLV test. The observation periods for the exposed cats was the period between the date of the first positive FeLV test of any cat in the household and the termination of this study. The total number of cat observation years for the unexposed and exposed cats was calculated by adding the individual observation periods of all cats in each group. The observation periods for the exposed and unexposed groups of cats were not the same as the exposed cats because the exposed cats had not been exposed for their entire life. To ensure that the difference in the observation periods did not bias our results, we also calculated the observation period for exposed cats in the same way as we did for the unexposed cats—according to their age. In this analysis there was a total of 558 cats, the additional 20 cats were cats that died before our study began and had not been tested for FeLV. The 558 cats were observed for their entire lives for a total observation period of 3,199 yr (an average of 5.7 yr—range 1–24 yr). We found 56 cases of LSA among these 558 exposed cats (30 FeLV-positive, 11 NPLSA and 15 whose status was unknown). The development of LSA per cat observation year was found to be the same (0.018 case) when the observation period was calculated from either (1) the time of FeLV exposure (41 cases of LSA per 2,334 cat observation years = 0.018), or (2) the ages of the cats (56 cases of LSA per 3,199 cat observation years = 0.017). Thus, the difference between the two methods of determining the observation period of the unexposed and exposed tested cats did not alter the conclusion of this study.

• †  $P < 0.001$ .

**Fig. 1** Examination of feline lymphosarcoma cells for FeLV antigens by the fixed-cell indirect IFA test. The test was done with a multivalent rabbit antiserum against disrupted FeLV that had known reactivity to FeLV gp70, p30, p15 and p12 antigens. *a*, Strong cytoplasmic fluorescence indicates presence of FeLV, but *b*, no such fluorescence is seen in NP LSA cells. Thus the NP LSA cells are devoid of replicating FeLV and FeLV gp70, p30, p15 and p12 expression.

A total of 1,612 FeLV-exposed and unexposed pet cats from all regions of the US were observed for the development of LSA (Table 3). A cat was classified as unexposed if the cat was FeLV-negative and if, according to the owner, the cat had not lived with any FeLV test-positive cat or with any cat which had an FeLV disease. The FeLV status of all cats was determined by the IFA test for FeLV antigens<sup>17</sup>. Of the 1,612 cats, 1,074 living in 96 households had never been exposed to FeLV and were uninfected with FeLV. These cats served as controls and were observed for a total of 3,235 cat observation years (an average of 3.1 yr per cat). None of the unexposed control cats developed LSA during this study. In contrast, the remaining 538 pet cats living in 23 households had been exposed to an FeLV-infected cat (Table 3). All of these exposed cats were tested for FeLV and 389 were found to be uninfected whereas 149 were infected. These cats were observed for a total of 2,334 cat observation years (an average of 4.3 yr per cat with a range of 1 to 6 yr) and 41 of these cats developed LSA; 30 of these LSAs were FeLV-positive and 11 were NP LSAs. The difference in the occurrence of NP LSA between the unexposed control cats and the exposed cats is highly significant by the  $\chi^2$  test,  $P < 0.001$ . In one household where there were four unrelated cats, one cat was infected with FeLV and died of FeLV-induced anaemia. What made the household unique was that all three uninfected cats died of NP alimentary LSA.

As infectious FeLV particles, FeLV antigens, and complete copies of FeLV provirus cannot be detected in feline NP LSAs by electron microscopy<sup>9</sup>, tissue culture isolation<sup>4,9,17</sup>, immunofluorescence (Fig. 1)<sup>4,17</sup>, RIA<sup>10,14,19</sup>, or by nucleic acid hybridization<sup>14,15,16</sup>, the aetiological role of FeLV in these tumours has been uncertain. In contrast to FeLV NP LSA cells, virtually all other oncovirus-transformed cells including FeSV- and MSV-transformed NP fibroblasts, Abelson MuLV and the acute avian leukaemia virus-transformed fibroblasts or leukaemia cells and bovine leukaemia cells are positive for at least the N-terminal viral gag protein by RIA even though they are negative for replicating virus<sup>22</sup>. We have recently reported that the FeLV-associated tumour-specific antigen, the feline oncornavirus-associated cell membrane antigen (FOCMA), is present on the surface of all FeLV- and FeSV-transformed, virus-producing cat cells, but not on non-transformed virus-producing cat cells. We found that FOCMA is also present on FeLV NP LSA cells suggesting that FeLV may play a role in the transformation of normal lymphocytes into NP LSA cells<sup>13,22,23</sup>. Our finding that there is a comparable epidemiological association between FeLV exposure and the development of both NP- and FeLV-positive LSAs (Koch's postulates have been fulfilled for the FeLV-positive LSAs)<sup>24</sup> supports the hypothesis

that FeLV may be the aetiological agent for most feline LSAs regardless of whether or not they express FeLV.

At least three possible hypotheses explain the mechanism by which a replicating oncovirus such as FeLV causes NP feline LSAs<sup>25</sup>. First, FeLV may be involved in the generation of a recombinant replication-defective leukaemogenic virus from cat cellular genes and FeLV provirus, similar to the Abelson MuLV, AK-T8 mink cell focus-inducing virus and several avian oncoviruses, although in these NP tumours some viral gag gene expression is present<sup>26-28</sup>. Second, only a fragment of the FeLV genome may be present as provirus in leukaemic cell chromosomes. If such a fragment was present, it would presumably be unable to code for the production of any detectable viral structural proteins, but may be able to initiate transformation<sup>29</sup>. Third, a 'hit and run' phenomenon might occur in which FeLV alters, but does not stably integrate into the chromosomes of the leukaemic cell.

Feline NP LSA is the only known example of a naturally occurring lymphoid tumour which develops after exposure to a leukaemogenic virus but in which no evidence of that leukaemogenic virus remains. NP LSAs may thus be valuable for the study of the basic mechanism by which viruses, chemicals or radiation induce transformation.

We thank R. Markovich, T. Paino and H. Perry for technical assistance, and Ms S. Passe for statistical analysis. We thank numerous practicing veterinarians and cat owners, especially Mrs S. Bernard, for assistance, and the National Veterinary Laboratory of Franklin Lakes, New Jersey for performing tests for FeLV and helping to obtain cats with FeLV non-producer lymphosarcomas. We also thank Drs Robert Gallo, Nancy Gutensohn and Peter Besmer for helpful discussions. This work was supported in part by grants and contracts from the NCI, The Cancer Research Institute, and the American Cancer Society. During this study W. D. H. was a Scholar and H. W. S. is a Special Fellow of the Leukemia Society of America.

## Interferon inhibits transformation by murine sarcoma viruses before integration of provirus

R. J. Avery, J. D. Norton, J. S. Jones,  
D. C. Burke & A. G. Morris

Department of Biological Sciences, University of Warwick,  
Coventry CV4 7AL, UK

Neoplastic transformation by C-type retroviruses requires synthesis of a DNA copy (the provirus) of the RNA genome and its integration into the host cell DNA. We have previously shown that interferon (IFN) can stably prevent transformation of murine fibroblasts by the Kirsten strain of murine sarcoma virus (KIMSV)<sup>1,2</sup>, a murine leukaemia virus (MLV). A series of cell clones (IFN clones), isolated in the presence of IFN ( $10^4$  U ml<sup>-1</sup>) from cultures of NIH-3T3 cells which had been treated with IFN, and then infected with KIMSV (KiMLV) in conditions where every cell was infected, were shown to be phenotypically untransformed. These untransformed cells did not produce virus or contain rescuable KIMSV. However, cells isolated using an identical procedure, but in the absence of IFN, were uniformly transformed and all produced KIMSV (KiMLV) or contained rescuable KIMSV<sup>2,3</sup>. It was concluded that IFN either prevents synthesis or integration of the provirus, or else that in the presence of IFN the provirus is integrated such that it is not expressed. We now show that five representative clones contain no detectable KIMSV proviral DNA, and also that the initial stages of infection by KIMSV (KiMLV) are inhibited by IFN treatment. IFN seems to act before integration, preventing either the synthesis or the integration of proviral DNA.

We initially sought to establish whether the IFN clones contained integrated KIMSV provirus in their cellular genomes, by hybridizing cell DNA with a representative <sup>3</sup>H-cDNA probe synthesized from purified KIMSV (KiMLV) RNA. As normal uninfected mouse DNA contains multiple copies of endogenous retrovirus sequences closely related to MLV genomes<sup>4</sup>, it was necessary to reduce the proportion of KiMLV cDNA sequences in the probe by annealing with KiMLV RNA. After this procedure the cDNA hybridized to a maximum level of about 16% with KiMLV RNA and 78% with KIMSV (KiMLV) RNA. It was then used as a cDNA probe for hybridization with various cell DNAs. The results (Table 1) show that there was some annealing of the cDNA probe with the DNA from uninfected NIH-3T3 cells, reflecting the inefficiency of the selection procedure, and that a much higher level of hybridization (~58%) occurred between the cDNA probe and the DNA from a non-producer, transformed cell line, CCl, which is known to contain a rescuable KIMSV genome.<sup>3</sup> The level of hybridization with DNA from the IFN clones was no higher than that seen with DNA from uninfected cells, strongly suggesting that the IFN clone DNAs do not contain integrated KIMSV proviral DNA.

The cell DNAs were further investigated for the presence of integrated provirus by restriction enzyme analysis using the Southern blotting procedure. Figure 1A shows the restriction map of unintegrated linear KIMSV DNA using endonuclease *Pst*I (details of the restriction mapping will be presented elsewhere). *Pst*I analysis of a number of KIMSV-transformed non-producer cell DNAs has shown each to contain the two large internal fragments *P*<sub>1</sub> (molecular weight  $2.6 \times 10^6$ ) and *P*<sub>2</sub> (molecular weight  $1.05 \times 10^6$ ) (Fig. 1A). These two internal *Pst*I fragments (representing 80% of the KIMSV genome) therefore provided a means of detecting integrated provirus. *Pst*I-digested cell DNAs were electrophoresed on an agarose gel and the fragments transferred to a filter which was then annealed with KIMSV (KiMLV) <sup>32</sup>P-cDNA to give the result shown in Fig. 1B.

Lane a shows the hybridization of the cDNA with the MLV-related sequences of uninfected cell DNA. In lane b, which contains a digest of CCl DNA, the two internal *Pst*I fragments (arrowed) are clearly visible against the background of hybridization. However, these fragments are absent from the IFN clone DNAs (c-g) showing that intact integrated provirus was not present. The use of other restriction enzymes, which cleave once or twice within the provirus, confirmed that no KIMSV-specific fragments were detectable in the IFN clone DNAs (data not shown).

Thus, we conclude that cells infected in the presence of IFN do not contain complete integrated proviral genomes and are unlikely to contain truncated forms of proviral DNA. IFN must therefore prevent transformation by KIMSV at a stage before integration.

The possibility that IFN was acting by inhibiting adsorption or penetration of the virus was investigated by determining the effect on KIMSV (KiMLV) transformation of IFN added after infection. Transformation was assayed by focus formation on monolayer cultures of C3H10T $\frac{1}{2}$  cells; the virus stock used contained an excess of KIMSV and focus formation using this stock at high dilution follows one-hit kinetics, that is, a focus is initiated by infection of a cell by KIMSV alone and enlargement of the focus is due to outgrowth from this cell alone rather than by virus spread or recruitment<sup>1</sup>. In such conditions, any effects of

Table 1 Hybridization of KIMSV cDNA with cellular DNAs

| IFN 61        | 76              | 16         |
|               | 73              | 14         |
| IFN 91        | 86              | 16         |
|               | 76              | 15         |

NIH-3T3 cells and a KIMSV-transformed non-producer line, CCl, were grown as described previously<sup>3</sup>. Details of the isolation of the IFN clones (IFN 49, 61, 81, 85 and 91) are given by Morris and Burke<sup>2</sup>. Cell DNAs were prepared by deproteinization with phenol/chloroform (1:1, v/v), spooling under ethanol (EtOH), RNase A digestion (50 µg ml<sup>-1</sup> for 1 h at 37 °C), further deproteinization, ether extraction and spooling under EtOH. The high molecular weight DNA was dissolved in 10<sup>-3</sup> M EDTA and sheared by sonication. Virion RNA (35S) was prepared from a purified KiMLV preparation containing excess KIMSV and used as a template for the *in vitro* synthesis of <sup>3</sup>H-cDNA by AMV reverse transcriptase essentially as described by Taylor *et al.*<sup>5</sup>. The reaction mixture contained 50 mM Tris pH 8.3, 40 mM KCl, 8 mM MgCl<sub>2</sub>, 5 µg calf thymus DNA primer, 100 µCi <sup>3</sup>H-TTP (42 Ci mmol<sup>-1</sup>), 0.2 mM dATP, dGTP, dCTP, 0.5 mM dithiothreitol, 4 mM Na pyrophosphate, 0.5 µg RNA and 7.5 units of AMV reverse transcriptase in a volume of 50 µl. Incubation was for 1 h at 37 °C. cDNA was purified by phenol/chloroform extraction, EtOH precipitation, alkali hydrolysis, a second EtOH precipitation; Sephadex G-100 chromatography and further EtOH precipitation. The cDNA was then selected by self-annealing and annealing with poly(rA) to remove anticomplementary (+ strand) sequences and oligo(dT) polymers, and annealed with KIMSV (KiMLV) RNA (at a ratio of 1:5 RNA:cDNA) to produce a representative cDNA probe. At this ratio 90% of the RNA hybridized to DNA. Finally the cDNA was hybridized with a 100-fold excess of KiMLV RNA to reduce the proportion of KiMLV cDNA sequences which can anneal with mouse DNA. Hybridizations were carried out in 2.4 M phosphate buffer (PB) (1.2 M Na<sub>2</sub>HPO<sub>4</sub>, 1.2 M NaH<sub>2</sub>PO<sub>4</sub>, pH 7.0) at 76 °C. These conditions, devised by D. E. Kohne (La Jolla Cancer Research Foundation), give a reproducible stimulation of the rate of hybridization (D. E. Kohne, personal communication). The cDNA was annealed with cell DNA, with the latter in at least 5 × 10<sup>6</sup>-fold excess, ensuring that a single integrated provirus would be in at least fivefold excess over the cDNA. The extent of hybridization with cDNA and reassociation of cell DNA (demonstrating the validity of each hybridization experiment) were determined by retention on hydroxypatite in 0.14 M PB at 61 °C.

IFN are due to an influence on the initial transformation event or on growth of transformed cells, rather than to effects on virus spread<sup>1</sup>. Murine C-type viruses penetrate and uncoat rapidly (within 80 min in NIH-3T3 cells at 37 °C)<sup>11</sup>, whereas at least 3 h are required for the antiviral effect of IFN to develop (ref. 12 and A.G.M., unpublished data). Thus, the addition of IFN to cells after their infection would be expected to have very little effect on transformation if its effects were exerted at this early stage. However, it was found that IFN added as much as 4 h after infection was virtually as effective at blocking transformation as pretreatment with IFN (Table 2). Even when added as late as 24 h post infection, IFN still inhibited focus formation to some extent (Tables 2 and 3) indicating that, in some infected cells, the IFN-sensitive stage was not complete. However, in reconstruction experiments treatment with IFN for 24 h had no effect on focus formation by cells stably transformed by KiMSV (KiMLV) and producing KiMSV (KiMLV) (data not shown),

**Fig. 1** A, Restriction endonuclease cleavage map of unintegrated linear KiMSV DNA. B, Hybridization of KiMSV (KiMLV) cDNA with endonuclease *Pst*I fragments of cell DNAs. High molecular weight DNA was prepared as described in Table 1 legend and 10- $\mu$ g samples were cleaved with an excess of endonuclease *Pst*I (Boehringer) and then run on a 1.0% agarose horizontal slab gel. DNA fragments were denatured *in situ* and transferred to a nitrocellulose filter (BA 85, Schleicher and Schuell) by the method of Southern<sup>6</sup>. For hybridization, a <sup>32</sup>P-labelled cDNA was synthesized as for the <sup>3</sup>H-cDNA probe (Table 1) except that pyrophosphate was omitted and actinomycin D (100  $\mu$ g ml<sup>-1</sup>) was included in the reaction mixture to suppress (+) strand cDNA synthesis<sup>7</sup> and <sup>3</sup>H-TTP was replaced by unlabelled TTP and dCTP by 125  $\mu$ Ci [ $\alpha$ -<sup>32</sup>P]dCTP (350 Ci mmol<sup>-1</sup>). The <sup>32</sup>P-cDNA was purified as described for the <sup>3</sup>H-cDNA (Table 1) and used without further selection. The filter was annealed with 2.5  $\times$  10<sup>6</sup> c.p.m. of <sup>32</sup>P-cDNA in a volume of 2.0 ml in a sealed polythene bag for 60 h using hybridization conditions described by Shank *et al.*<sup>8</sup>. Unlabelled KiMLV RNA (5.0  $\mu$ g ml<sup>-1</sup>) was included in the hybridization medium to suppress the level of background hybridization of cDNA with KiMLV-related sequences present in mouse DNA. After annealing, the filter was washed<sup>8</sup> and treated with RNase A (10  $\mu$ g ml<sup>-1</sup>) in 15 mM NaCl, 1.5 mM Na<sub>3</sub> citrate at 37 °C for 20 min. The filter was exposed to X-ray film (Fuji RX) at -70 °C for 1 week using a Dupont Cronex 'Lightning Plus' intensifying screen. a, Uninfected NIH-3T3 DNA; b, CCI DNA; c-g, DNA from IFN clones<sup>2</sup>, IFN 49, 61, 81, 85 and 91 respectively. Molecular weights of restriction fragments were determined using *Eco*RI<sup>9</sup> and *Hind*III<sup>10</sup> fragments of bacteriophage  $\lambda$  DNA as size markers.

**Table 2** Effect of IFN treatment before and after infection with KiMSV (KiMLV)

| Time of IFN addition (h) | Mean no. of foci per plate |
|--------------------------|----------------------------|
| -24                      | 0.5                        |
| +1                       | 0                          |
| +2                       | 1.0                        |
| +4                       | 0                          |
| +6                       | 2.5                        |
| +24                      | 10.5                       |
| None                     | 13.25                      |

IFN (10<sup>4</sup> U ml<sup>-1</sup> and 2  $\times$  10<sup>8</sup> U mg<sup>-1</sup>) was added to cultures of C3H10T $\frac{1}{2}$  cells at the times indicated and removed 24 h later. All cultures were infected with 30 FFU of KiMSV (KiMLV) at 0 h. Transformed foci were scored 10 days later.

**Table 3** Effect of IFN treatment on KiMSV (KiMLV) infection of serum-deprived cells

| Period of serum deprivation (h) | Period of IFN treatment (h) | Mean no. of foci per culture |
|---------------------------------|-----------------------------|------------------------------|
| None                            | None                        | 27                           |
| -24 to 264                      | None                        | 0                            |
| None                            | -24 to 0                    | 0                            |
| None                            | 24 to 48                    | 10.5                         |
| -24 to 72                       | None                        | 12                           |
| -24 to 72                       | 24 to 48                    | 0                            |

Cultures of C3H10T $\frac{1}{2}$  cells<sup>13</sup>, otherwise maintained in medium containing 5% serum, were shifted into medium containing 0.25% serum (serum deprivation) and treated with IFN (10<sup>4</sup> U ml<sup>-1</sup>) for periods as indicated. All cultures were infected at 0 h with KiMSV (KiMLV) at 30 FFU per culture. Transformed foci were scored 10 days later.

showing that the effect was not due to an inhibition of growth of transformed cells. These data indicated that IFN probably does not act by inhibiting adsorption, penetration or uncoating of the virus.

An extension of this experimental approach suggested that IFN acts at or after provirus synthesis. In cells arrested in G<sub>0</sub> by serum deprivation, C-type virus replication is blocked<sup>14,15</sup>. It seems that in such conditions synthesis of proviral DNA begins but is not completed and integration does not occur. Cultures of normal mouse fibroblasts (C3H10T $\frac{1}{2}$ ) were blocked in G<sub>0</sub> by prolonged serum deprivation and then infected with KiMSV (MLV) (30 FFU (focus-forming units) per culture). Addition of serum 48 h later allowed transformation (again scored by focus formation), showing the block to be reversible. However, when IFN was added 24 h post infection, so that it is present for the 24-h period before serum addition, transformation was essentially completely prevented (Table 3). A similar IFN treatment of cells which had not been serum deprived was much less effective in preventing transformation. This suggests that IFN acts at, or later than the stage blocked by serum deprivation.

It therefore seems that IFN can block infection by C-type viruses at a stage after uncoating but before integration of the provirus. This is not due to the cell growth inhibitory effect of IFN as in these and other experiments IFN had no significant effect on the growth of the cells used; nor is it likely to be an effect of IFN on translation of viral mRNA, as translation of input genomic RNA is probably not significant in the virus life cycle<sup>16-18</sup>.

This effect of IFN is at least superficially similar to the Fv-1 restriction phenomenon<sup>19-21</sup> in which the Fv-1 gene product appears to prevent integration of proviral DNA; it may be that here IFN is acting in a way that is analogous to the effect of the Fv-1 gene product.

## Heterogeneity of poly(I).poly(C)-induced human fibroblast interferon mRNA species

Pravinkumar B. Sehgal & Anurag D. Sagar

The Rockefeller University, New York, New York 10021

Three classes of human interferons (IFNs) have been defined on the basis of their immunological properties: the 'Le' or ' $\alpha$ ' IFN, mainly derived from leukocyte or lymphoblastoid cells; the 'F' or ' $\beta$ ' IFN, mainly derived from fibroblast cultures; and the 'T', 'immune' or ' $\gamma$ ' IFN, mainly derived from mitogen- or antigen-stimulated lymphoid cells<sup>1</sup>. Whereas several individual species of Le IFN have been purified to homogeneity<sup>2-4</sup>, it is generally considered that F IFN represents a single protein<sup>5,6</sup>. Thus current efforts to clone human fibroblast IFN mRNA sequences are based on the observation that F IFN mRNA sediments in sucrose gradients as a single RNA species of size corresponding to 12-14 S (refs 7-10). We show here, using gel electrophoresis of mRNA, that two populations of translationally active human fibroblast IFN mRNA molecules exist—an abundant '14 S' species and a scarce '11 S' species. Microinjection of either species of mRNA into *Xenopus* oocytes leads to the synthesis of biologically active F-type human IFN. These data agree with and complement recent RNA hybridization studies of Weissenbach *et al.*<sup>10</sup>.

Polyadenylated IFN mRNA was prepared from diploid human fibroblast cultures (FS-4 strain) exposed to poly(I).poly(C) and cycloheximide for 4 h as described earlier<sup>7,11</sup>. In some experiments the induced cells were fractionated using hypotonic swelling and Dounce homogenization<sup>7,11</sup> and cytoplasmic polyadenylated RNA was prepared. Appropriate amounts of IFN mRNA preparations were mixed with <sup>32</sup>P-labelled HeLa cytoplasmic RNA, the samples made 6 M in urea, heated at 95 °C for 2 min, cooled rapidly in an ice bath and electrophoresed through a cylindrical agarose-6 M urea gel<sup>12,13</sup>. Adjacent slices in the appropriate region of the gel were pooled, the RNA eluted and assayed for IFN mRNA activity by microinjection in oocytes of *Xenopus laevis*. Figure 1a shows the electrophoretic profile of translationally active IFN mRNA in preparations of cellular polyadenylated RNA from induced FS-4 cells. Figure 1b shows a similar profile of IFN mRNA in preparations of cytoplasmic polyadenylated RNA. At least two populations of IFN mRNA are clearly resolved in each

**Fig. 1** Electrophoresis of human fibroblast IFN mRNA preparations through agarose-6 M urea gels. Polyadenylated RNA preparations obtained from FS-4 cultures induced with poly(I).poly(C) (30  $\mu$ g ml<sup>-1</sup>, P.-L. Biochemicals) and cycloheximide (50  $\mu$ g ml<sup>-1</sup>, Calbiochem) for 4 h were mixed with an appropriate amount of <sup>32</sup>P-labelled HeLa cell cytoplasmic RNA in 50  $\mu$ l distilled water. The samples were made 6 M in urea (Eastman or Schwarz-Mann) and 50 mM in NaCl, and 5  $\mu$ l glycerol saturated with bromophenol blue was added. The samples were then heated at 95 °C for 2 min, cooled rapidly in an ice bath and electrophoresed through a 2.5% (a) or 2% (b) agarose (Biorad)-6 M urea cylindrical gel (0.6  $\times$  11 cm) in half-strength Loening's buffer (Tris-HCl 0.02 M, sodium acetate 0.01 M, EDTA 0.001 M, pH 7.8) at 4 °C and 5-6 mA per tube ( $\sim$ 8 V cm<sup>-1</sup>) using the modified<sup>13</sup> procedure of Locker<sup>12</sup>. After electrophoresis, the gels were sliced manually into 1-mm slices and the <sup>32</sup>P content of each slice monitored by Cerenkov counting to locate the positions of 28 S, 18 S, 5 S and 4 S marker RNA species (O). The MWs for marker RNA species were taken to be 1.75  $\times$  10<sup>6</sup>, 0.605  $\times$  10<sup>6</sup>, 3.9  $\times$  10<sup>4</sup> and 2.6  $\times$  10<sup>4</sup> for 28 S, 18 S, 5 S and 4 S RNA species, respectively<sup>29</sup>. Adjacent slices in the appropriate regions of the gel were pooled (2 slices per pool) and the RNA eluted as described elsewhere<sup>13</sup>. The RNA recovery was in the 50-80% range as estimated by the recovery of <sup>32</sup>P-labelled RNA present in each slice. Each RNA pellet was washed with 2 M LiCl and then with ethanol, dried and dissolved either in 2  $\mu$ l (a) or in 5  $\mu$ l (b) sterile distilled water. A 2- $\mu$ l aliquot of each RNA sample was microinjected into 15-20 oocytes of *X. laevis* and the oocytes incubated in 0.2 ml Barth's medium for  $\sim$ 40 h<sup>11,30</sup>. The IFN content (●) of the oocyte incubation medium (ref. 31; P.B.S., in preparation) was estimated by a semi-microassay on GM258, GM2767 or FS-4 cells with VSV as the challenge virus<sup>32,33</sup>. All IFN titres are expressed in terms of the 69/19 reference standard for human IFN. a, Cellular polyadenylated RNA (37  $\mu$ g) electrophoresed through a 2.5% agarose-6 M urea gel. b, Cytoplasmic polyadenylated RNA (30  $\mu$ g) electrophoresed through a 2% agarose-6 M urea gel.

case: an abundant species of length 1,100–1,200 residues (corresponding to a sedimentation value of 14 S using the relationship  $MW/330 = \text{number of residues} = 4.7 S^{2.1}$ ) and a less abundant species of length 700–800 residues (corresponding to a sedimentation value of 11 S). For convenience we refer to these two species of mRNA as the '14 S' and '11 S' IFN mRNAs.

In the experiment illustrated in Fig. 1b only 40% of each RNA sample eluted from gel slices was assayed in oocytes. The remaining 60% of RNA corresponding to the individual 14 S and 11 S species was denatured once more and electrophoresed individually through another agarose-urea gel. The second set of gels was then sliced and appropriate gel slices assayed for IFN mRNA activity. Both the 14 S and 11 S species re-electrophoresed as RNA corresponding to 14 S and 11 S respectively (data not shown).

We have electrophoresed a sample of IFN mRNA through an agarose- $\text{CH}_3\text{HgOH}$  gel<sup>14–17</sup> in fully denaturing conditions (10 mM  $\text{CH}_3\text{HgOH}$ ). Figure 2 indicates that the two populations of IFN mRNA can also be resolved when RNA electrophoresis is carried out in stringent denaturing conditions. Whereas a 1.75% agarose gel was used in the experiment illustrated in Fig. 2, we now routinely use a 2% agarose gel. In these conditions the abundant species is of length 1.3 kilobases (six determinations,  $\pm 40$  residues, s.e. of mean), whereas the less abundant species is of length 0.9 kilobases (six determinations,  $\pm 40$  residues).

The translation product of the 14 S and 11 S mRNA species has been characterized as the human F-type IFN (Table 1). The antiviral activity synthesized by *Xenopus* oocytes in response to

**Fig. 2** Electrophoresis of a human fibroblast IFN mRNA preparation through an agarose- $\text{CH}_3\text{HgOH}$  gel. Cellular polyadenylated RNA (45  $\mu\text{g}$ ) obtained from induced FS-4 cells was mixed with  $^{32}\text{P}$ -labelled marker RNA and was made 10 mM in  $\text{CH}_3\text{HgOH}$  (stock 1.27 M, Alfa Division, Ventron) in half-strength borate buffer (full strength corresponds to: 0.1 M boric acid, 6 mM sodium borate, 1 mM EDTA, 10 mM sodium sulphate, pH 8.2) in a total volume of 50  $\mu\text{l}$  and was allowed to stand for 5 min at room temperature. 5  $\mu\text{l}$  of glycerol saturated with bromophenol blue was then added and the RNA electrophoresed through a 1.75% agarose-10 mM  $\text{CH}_3\text{HgOH}$  cylindrical gel (0.6  $\times$  11 cm) in borate buffer at room temperature (4 mA per tube; 3.5  $\text{V cm}^{-1}$ ) until the dye was close to the bottom of the tube gel (5 h; ref. 17). After electrophoresis the gel was placed in 100 ml of a solution containing 100 mM  $\beta$ -mercaptoethanol and 0.01 M Tris-HCl, pH 7.4, for 40 min on a rotary shaker at room temperature. The gel was then sliced manually, the locations of marker RNA (O) monitored by Cerenkov counting, RNA in appropriate regions of the gel eluted (the elution buffer contained 1 mM dithiothreitol<sup>13</sup>), dissolved in 2  $\mu\text{l}$  distilled water and assayed for IFN mRNA activity (●) as indicated in Fig. 1 legend.

**Fig. 3** Hybridization analysis of human fibroblast IFN mRNA species using  $^{32}\text{P}$ -labelled *Pst*I/*Bgl*II fragment of the IFN cDNA insert in clone TpIF319-13. Cellular polyadenylated RNA (12  $\mu\text{g}$ ) obtained from induced FS-4 cells was glyoxylated in 50% dimethylsulphoxide at 50  $^{\circ}\text{C}$  for 45 min, electrophoresed through a 1.5% agarose slab gel in 10 mM sodium phosphate buffer (pH 6.5) until the bromophenol blue dye had moved  $\sim 15$  cm from the origin.  $^{32}\text{P}$ -labelled HeLa cytoplasmic RNA was also glyoxylated and electrophoresed in an adjacent slot in the gel. After electrophoresis the RNA was transferred to APT-paper and hybridized as described by Alwine *et al.*<sup>34</sup>  $^{32}\text{P}$ -labelled *Pst*I/*Bgl*II DNA fragment of clone TpIF319-13 ( $1.7 \times 10^5$  Cerenkov c.p.m.) was heat-denatured (65  $^{\circ}\text{C}$  for 10 min in 50% formamide) and hybridized to the RNA-containing paper in 1 ml of hybridization buffer (50% formamide, 0.75 M NaCl, 0.075 M sodium citrate, 1X Denhardt's solution, 20 mM sodium phosphate buffer, pH 6.5, and 0.2% sodium dodecyl sulphate) for 72 h at 37  $^{\circ}\text{C}$ . The hybridized DNA was detected by autoradiography. The presence of the 0.9- and 1.3-kilobase translatable IFN mRNA species in the mRNA preparation used in this experiment was verified using the procedure in Fig. 2 legend. Lane a, IFN mRNA preparation; lane b,  $^{32}\text{P}$ -labelled HeLa cytoplasmic RNA. kb, Kilobases.

microinjection with individual 14 S and 11 S mRNA species is completely neutralized by anti-F IFN antiserum but is largely unaffected by anti-Le IFN antiserum.

The results presented here are directly relevant to the interpretation of recent data obtained using cloned human fibroblast IFN mRNA sequences<sup>8–10,18</sup>. Weissenbach *et al.*<sup>10</sup> have described plasmids containing cDNA inserts (in pBR322) derived from polyadenylated RNA extracted from poly(I).poly(C)-induced human diploid fibroblasts (FS-11 strain). DNA from one of these clones (clone A341), which has been identified as an 'interferon' clone, hybridizes to two populations of polyadenylated RNA from induced cells: an RNA of length 1,100–1,200 residues hybridizes strongly to this DNA probe whereas another species of length  $\sim 750$  residues hybridizes weakly. Their data do not allow one to determine whether the two populations of RNA function as translationally active IFN mRNA species as sucrose gradient sedimentation analysis by these investigators reveals a single peak of biologically active IFN mRNA sedimenting at 12–14 S (corresponding to a length of 1,100–1,200 residues). The enhanced resolution of gel electrophoretic analyses of IFN mRNA described here clearly

**Table 1** Neutralization of IFNs synthesized by *Xenopus* oocytes in response to microinjection with separated 14 S and 11 S mRNA species

RNA recovered from gel slices corresponding to the peaks of 14 S and 11 S IFN mRNA as described in Fig. 1a was injected into groups of oocytes (20–30 per group), which were then incubated in 0.2 ml Barth's medium for 30–40 h at room temperature. The clarified oocyte homogenate was used to set up neutralization assays<sup>28</sup>. Briefly, 100- $\mu$ l aliquots of a 1:4 or 1:5 dilution of the oocyte homogenate in cell culture medium (Eagle's minimal essential medium containing heat-inactivated fetal bovine serum, 10% v/v) was mixed with 2  $\mu$ l (expts 2, 3 and control IFN preparations or 10  $\mu$ l (expt 1) anti-F IFN antiserum (batch 2 + 282) or 10  $\mu$ l of a 1:10 dilution of anti-Le IFN antiserum (batch 903) or both. Controls free of antiserum were mixed with an appropriate volume of culture medium. The samples were incubated for 60–90 min at 37 °C and serial twofold dilutions (50- or 100- $\mu$ l aliquots) of each sample were added to confluent, 1-day-old monolayers of human GM258 cells in multiwell microtitre dishes. The cultures were incubated for 20–24 h at 37 °C, the IFN- and antiserum-containing medium was removed and replaced with fresh culture medium containing vesicular stomatitis virus (VSV). The residual IFN titre represents the reciprocal of the highest dilution of the original oocyte homogenate that protected GM258 cell monolayers and is expressed in terms of the 69/19 reference standard for human IFN. Fibroblast IFN used to test the specificity of the antisera was prepared by superinduction of FS-4 cell cultures with poly(I):poly(C), cycloheximide and actinomycin D<sup>33</sup>, whereas the leukocyte IFN used was prepared by induction of human peripheral blood buffy coat preparations with Sendai virus.

demonstrates that both populations of RNA represent translationally active mRNA species for human F-type IFN.

Human fibroblast IFN mRNA sequences have also been cloned by a group of Japanese investigators<sup>8,9,18</sup>. The DNA restriction map and nucleotide sequence obtained by Taniguchi *et al.* (clone TpIF319-13, ref. 18) is different from that for clone A341 (M. Revel and M. Zeevi, personal communication). Therefore it seemed likely that clone A341 would correspond to the 1.3-kilobase IFN mRNA and that clone TpIF319-13 would correspond to the 0.9-kilobase mRNA species. Figure 3 presents a test of this hypothesis. Polyadenylated RNA obtained from induced FS-4 cells was denatured by glyoxylation, electrophoresed in a 1.5% agarose slab gel, transferred to APT-paper and hybridized to <sup>32</sup>P-labelled, nick-translated, 359-base pair, *Pst*I/*Bgl*II DNA fragment of the cDNA insert in clone TpIF319-13. This DNA fragment corresponds to the middle and carboxy-terminal portions of the human fibroblast IFN coding sequence. It can be seen from Fig. 3 that this probe hybridized exclusively to an RNA species of approximate length 0.9 kilobase. Thus the 1.3-kilobase fibroblast IFN mRNA has a sequence which is substantially different from that of clone TpIF319-13.

Although we have resolved two size classes of human F IFN mRNA by electrophoresis in agarose gels, we cannot exclude further sequence heterogeneity within each size class.

Data on the effect of glycosylation inhibitors on the physical properties of fibroblast IFN synthesized in their presence (ref. 19; Y. K. Yip and J. Vilček, personal communication) as well as recent protein fractionation studies (refs 20, 21; E. Knight Jr,

personal communication) suggest the existence of more than one human F-type IFN protein. This heterogeneity may reflect the existence of distinct chromosomal genes for fibroblast IFN such as on human chromosome 2 or 5 or 9 (refs 22, 23). Alternatively, the heterogeneity may arise from the existence of alternative pathways for processing the primary transcript of IFN gene(s) in the cell nucleus.

The existence of multiple species of human leukocyte (Le)-type human IFNs as well as of murine IFNs has been clearly demonstrated<sup>2-4,24,25</sup>. Furthermore, recent nucleic acid cloning experiments demonstrate the existence of at least two distinct sequences for human Le IFN<sup>26,27</sup>. Gel electrophoretic analyses of IFN mRNA species from these sources may be highly instructive. It is likely that IFN genes constitute a large multi-genic family of inducible genes which code for cellular proteins with antiviral, anticellular and immunomodulatory effects in eukaryotic cells.

This investigation was partly stimulated by a seminar given by Dr Michel Revel at The Rockefeller University on 18 February 1980. We thank Dr T. Taniguchi for the <sup>32</sup>P-labelled *Pst*I/*Bgl*II DNA fragment of clone TpIF319-13 and Mr Benjamin Neel for assistance in carrying out the blot-hybridization experiment. We also thank Drs I. Tamm, J. Vilček, E. A. Havell, E. Knight and M. Zeevi for helpful discussions, Drs J. Vilček and E. A. Havell for the anti-IFN antisera, Dr W. E. Stewart II for a sample of human Le IFN and Drs T. Taniguchi, M. Revel and K. Cantell for preprints. We thank Mr Ira Augenzucker for technical assistance. This investigation was supported by NIAID, DHEW grant AI-16262. P.B.S. is the recipient of a Junior Faculty Research Award from the American Cancer Society.

**Note added in proof:** In accordance with current guidelines for interferon nomenclature [*Nature* **286**, 110 (1980)], we suggest that the translation product of the 0.9-kilobase IFN mRNA (Fig. 2) be designated human interferon- $\beta_1$  and that of the 1.3-kilobase IFN mRNA be designated human interferon- $\beta_2$ .

## Interferon-dependent induction of mRNA activity for (2'-5')oligo-isoadenylate synthetase

Lester Shulman & Michel Revel

Department of Virology, Weizmann Institute of Science, Rehovot, Israel

At least three different enzymes involved in the regulation of protein synthesis are induced in a variety of cells by interferon (IFN)<sup>1-5</sup>. Sensitive assays for these enzymes have been developed and used to establish the specificity, dose dependence and time course of their induction by IFN<sup>5-8</sup>. One of these enzymes, the oligo-isoadenylate synthetase E, whose product (2'-5')pppApApA<sup>9</sup> activates the latent ribonuclease F<sup>10-11</sup>, is increased over 50-fold after IFN treatment. We describe here the assay for an mRNA from IFN-treated mouse L cells, that produces oligo-isoadenylate synthetase activity when injected into *Xenopus* oocytes. This mRNA is found in the cells only after exposure to IFN. The mRNA increases in mouse L cells with the same time course as the enzyme activity itself. In particular, there is a 3-h lag period between IFN addition and the onset of enzyme and mRNA accumulation. Using anti-IFN antibodies, we show that during this lag period the continued interaction of IFN with the cells is necessary for the full induction of the oligo-isoadenylate synthetase.

Poly(A)-containing RNAs<sup>12</sup> were prepared from cytoplasmic extracts of L929 monolayer cultures which had been exposed for different times to 200 U ml<sup>-1</sup> mouse IFN<sup>5</sup>. The RNAs were injected into *Xenopus laevis* oocytes<sup>13</sup>, extracts from these oocytes were added to poly(rI)·(rC)-agarose beads, which were then incubated with [ $\alpha$ -<sup>32</sup>P]ATP to measure the synthesis of (2'-5')oligo-isoadenylate as previously described<sup>5</sup>. In parallel, the cellular level of the oligo-isoadenylate synthetase was measured in the NP40 cytoplasmic extracts from the same cultures (Fig. 1a). Formation of the phosphatase-resistant (2'-5')(Ap)<sub>n</sub>A oligonucleotides is only seen with extracts from IFN-treated cells. Figure 1b (lane 1) shows that extracts of *Xenopus* oocytes do not normally form any (2'-5')ApA by themselves (see also ref. 6), but (2'-5')ApA synthesis appeared clearly in extracts of oocytes injected with poly(A)<sup>+</sup>-mRNA from IFN-treated cells (lane 4). Identification of this activity in injected oocytes, with the IFN-induced oligo-isoadenylate synthetase, is based on the following arguments: (1) Formation of the (2'-5')ApA results from an enzymatic activity which binds to the poly(rI)·(rC)-agarose beads, no significant activity being detected without this purification step. (2) The activity appears only if mRNA from IFN-treated cells is injected into the oocytes (compare lanes 2 and 4 in Fig. 1). (3) The phosphatase-treated products, labelled with [ $\alpha$ -<sup>32</sup>P]ATP, co-migrated in several thin-layer chromatography and electrophoresis systems<sup>9,10</sup>, with chemically synthesized (2'-5')ApA markers. The predominance of dimers in the oocyte products is due to the low level of enzyme used; the same is found when a limited reaction is carried out with purified synthetase<sup>10</sup>. (4) Finally, the products of a large-scale reaction (with 1 ml oocyte extract instead of the 0.02 ml routinely used) inhibited Mengo RNA translation in L-cell extracts (Table 1) proving that biologically active (2'-5')oligo(A) is formed. In these conditions (2'-5')oligo trimers were seen by electrophoresis of the phosphatase-treated products (not shown). No translational inhibition was found with the products of mRNA from cells not treated with IFN.

In conditions where (2'-5')oligo(A) synthesis is proportional to the amount of extract used, we compared the oligo-iso-

adenylate synthetase activity in L cells and in mRNA-injected oocytes (Table 1, right). The enzyme activity produced in oocytes by injection of mRNA from L cells treated for 8 h with IFN represents ~1% of the enzyme activity present in the same volume of cell extract from which the mRNA was prepared. We verified that untreated-cell mRNA, which does not yield synthetase activity, is not inhibitory in our assay: 33,400 c.p.m. (2'-5')ApA were formed with extracts of oocytes injected with 1  $\mu$ g of 8h-mRNA, against 3,600 c.p.m. for 0h-mRNA, and 45,100 c.p.m. for the mixture of 0h- and 8h-mRNA. The accumulation of oligo-isoadenylate synthetase in L cells exposed to IFN is, therefore, accompanied by a proportional increase in an mRNA yielding this enzymatic activity in the oocyte assay. In similar experiments, we have found that exposure of human lymphoblastoid Namalva cells to leukocyte

**Fig. 1** Formation of active oligo-isoadenylate synthetase by translation of IFN-induced mRNA in *Xenopus* oocytes. L929 monolayer cultures in minimal Eagle's medium with 8% calf serum were exposed for 0, 3 or 8 h at 37°C to 200 U ml<sup>-1</sup> mouse IFN (induced in L cells by Newcastle disease virus and purified at 10<sup>7</sup> U per mg protein<sup>5</sup>). Cells from seven plates were washed with 35 mM Tris-HCl pH 7.5, 140 mM KCl, 3 mM Mg acetate and lysed with 0.5% Nonidet P40 (NP40) in 5 mM Tris-HCl pH 7.8, 100 mM NaCl, 3 mM Mg acetate (2 ml per plate). After 30 min, nuclei were removed by centrifugation at 2,000g for 10 min. **a**, Enzyme activity in cell extracts. 20  $\mu$ l cytoplasmic extract was mixed with 50  $\mu$ l poly(rI)·(rC)-agarose beads (P.L. Biochemicals). After 10 min at 30°C, unbound proteins were removed by washing the beads twice in 20 mM HEPES buffer pH 7.5, 120 mM KCl, 5 mM MgCl<sub>2</sub>, 1 mM dithiothreitol, 10% glycerol (Buffer B). Beads were incubated in 10  $\mu$ l of 2.5 mM [ $\alpha$ -<sup>32</sup>P]ATP (0.24 Ci mmol<sup>-1</sup>) and 2.5 mM dithiothreitol for 20 h at 30°C. Beads were centrifuged down, washed with 10  $\mu$ l water and the two supernatants combined. 6  $\mu$ l were treated with bacterial alkaline phosphatase and subjected to paper electrophoresis at pH 3.5 (4 kV, 3 h) and autoradiography as previously described<sup>3</sup>. Positions of (2'-5')ApA and ApApA were indicated by synthetic markers. Extracts of cells treated 0 h (lane 1), 3 h (lane 2) and 8 h (lane 3) with IFN are shown. **b**, Enzyme synthesized in oocytes. To the cytoplasmic extracts, 3 mM EDTA and 0.5% dodecyl sulphate were added and RNA was extracted three times by 1 vol phenol-chloroform-isoamylalcohol (50:50:1), precipitated with 2 vol ethanol and the poly(A)<sup>+</sup> sequences was purified on oligo(dT)-cellulose<sup>12</sup>. Groups of 10 *Xenopus* oocytes were injected with 50 ng RNA (in 50 nl) per oocyte as described by Gurdon *et al.*<sup>13</sup>. The oocytes were kept in 0.15 ml Barth's medium for 20 h and then homogenized with 0.5 ml Buffer B. Aliquots (20  $\mu$ l) of homogenate were used to assay (2'-5')oligo(A) synthesis as above. Lane 1, water-injected oocytes; lanes 2, 3 and 4, oocytes injected with mRNA from L cells, treated 0, 3 and 8 h with IFN, respectively. UV spots of markers are shown. All radioactive spots were cut out and counted by Cerenkoff radiation in a scintillation counter. Results are given in Table 1.

**Fig. 2** Delayed effect of anti-IFN antibodies on oligo-isoadenylate synthetase E induction by IFN. Monolayer cultures of mouse L929 or human foreskin FS11 cells (about  $3 \times 10^4$  cells per well of a 96-well microplate) received  $50 \text{ U ml}^{-1}$  mouse L-cell IFN or  $15 \text{ U ml}^{-1}$  human fibroblast IFN<sup>19</sup>, respectively. The level of enzyme E was measured as before<sup>5</sup>, at the time indicated on the abscissa. Antibodies to mouse L-cell IFN or antiserum to human fibroblast IFN obtained in rabbits<sup>19</sup> were added (at dilutions of 1/100 and 1/20, respectively, see Table 2) at the indicated times after IFN addition. The lower activity of the L cells reflects use of less radioactive ATP in this assay.

IFN also induces mRNA yielding oligo-isoadenylate synthetase activity in the oocyte assay (not shown).

In cell cultures exposed to IFN, induction of the oligo-isoadenylate synthetase does not start immediately on addition of IFN but is preceded by a 2–3-h lag period (ref. 5 and Fig. 2). This lag is characteristic of IFN action and does not depend on the amount of IFN used. With the oocyte assay we compared the level of mRNA activity for the oligo-isoadenylate synthetase, at 3 and 8 h after IFN addition. Although some mRNA activity can be detected at 3 h (Fig. 1b, lane 3), over 90% of the mRNA present at 8 h is formed during the 3–8-h period, whereas less than 10% is made from 0–3 h after IFN addition (Table 1). A more than 10-fold increase in mRNA activity from 3 to 8 h could also be calculated from the translation inhibition experiment shown in Table 1: 50% inhibition was seen at a 1:1,000 dilution for the 3-h mRNA products and at 1:20,000 for the 8-h mRNA products. Like enzyme synthesis, induction of the mRNA seems, therefore, to be a slow process.

This delayed response to IFN prompted us to examine how long IFN has to interact with the cells to trigger oligo-isoadenylate synthetase induction. Antibodies against mouse IFN were added to L-cell cultures to interrupt the action of IFN at different times after its addition. When added together with IFN, the antibodies blocked completely induction of oligo-isoadenylate synthetase, whereas replication of vesicular stomatitis virus (VSV) was able to proceed normally as in the absence of IFN (Table 2). Antibodies, therefore, block the cell response to IFN but do not impair other cell functions such as viral replication. The effect is specific as anti-mouse IFN did not inhibit oligo-isoadenylate synthetase induction by human IFN in human cells and, conversely, anti-human fibroblast IFN did not inhibit the effect of mouse IFN on L cells (Table 2). Figure 2 shows that, in mouse and human cells, the delayed addition of antibodies, at 1, 2 or 3 h after IFN addition, can still interrupt the already initiated process of enzyme induction. Enzyme accumulation starts but stops at a certain level. The enzyme level reached increases with the time between IFN and anti-IFN additions. Thus, when anti-mouse IFN is added to L cells 3 h after IFN, the induction proceeds for 8 h but then stops. Thus, to complete the induction process, IFN has to act for more than 3 h,

that is, beyond the lag period. In human foreskin cells, the kinetics of synthetase induction are somewhat slower than in mouse L cells<sup>5</sup>, and as shown in Fig. 2, the inhibition by delayed addition of antibodies is even more pronounced than in L cells. The antiviral effect of IFN against VSV replication in these cells was also inhibited by antibodies against human IFN, 3 h after IFN addition (not shown).

Antibodies do not penetrate inside living cells<sup>14</sup>. The inhibitory effects of anti-IFN added 2 or 3 h after IFN probably results, therefore, from neutralization of IFN molecules still present outside the cell. Although IFN binds rapidly to cells<sup>15</sup>, it does not seem to enter the cell rapidly, as already suggested by experiments with antibodies to the chromosome 21-coded human IFN receptor<sup>16,17</sup>. The lag period in the oligo-isoadenylate synthetase induction could then be explained by a prolonged action of IFN outside the cell, the resistance to neutralization by antibodies developing only just before the enzyme and its mRNA activity measured in the oocyte assay start to accumulate in the cytoplasm of the cells. The parallel increase in translatable mRNA and in enzyme observed in our

**Table 1** Induction by interferon of mRNA for oligo-isoadenylate synthetase

| Time after IFN addition (h) | Oligo-isoadenylate synthetase activity      |       |  |               |

IFN and anti-IFN antibodies were added together to the cells, in the conditions described in Fig. 2 legend. The enzyme assay was carried out after 8 h for mouse L929 cells and after 14 h for human foreskin FS11 cells. Where indicated, mouse cells were infected at 8 h with 4 PFU per cell VSV and the virus growth was measured 24 h later. PFU, plaque-forming units.

experiments suggests that the main control of enzyme accumulation is formation of new mRNA. This is consistent with the inhibition of induction by actinomycin D, and by cycloheximide, which also indicates that there is no activation of a preformed enzyme in the cells<sup>5</sup>. We had previously reported<sup>3</sup> that actinomycin D added 2 h after IFN does not block any more oligo-isoadenylate synthetase induction in L cells: this seems to contradict the more than 10-fold increase in mRNA measured by the oocyte assay from 3 to 8 h after IFN addition. On the other hand, the results obtained by delayed antibody addition are in line with the kinetics of mRNA accumulation. Actinomycin D causes a phenomenon of superinduction<sup>5</sup>, and the normal level of enzyme found when actinomycin D is added at 2 h may reflect a more efficient expression of a smaller amount of mRNA. Actinomycin D cannot, therefore, be easily used to analyse the induction process.

The mRNA assay described here should facilitate the study of the mechanism by which IFN induces oligo-isoadenylate

synthetase, a process tightly correlated with its biological activity<sup>5,7,8</sup>. An important question still to be solved is whether the mRNA product is the enzyme itself, a regulatory factor or a combination of polypeptides. This question cannot be answered until the polypeptide structure of the enzyme is determined. Farrell *et al.*<sup>18</sup> have described the synthesis of some proteins by translation of IFN-induced mRNAs in reticulocyte lysates, but could not identify any enzymatic activity. The oocyte assay demonstrates for the first time that IFN induces in the cells an mRNA involved in the synthesis of oligo-isoadenylate synthetase.

We acknowledge helpful suggestions from Dr H. Sorek and D. Givon and the technical assistance of Ms Sara Tzur. Synthetic markers for the assay were given by Dr S. Rapoport and Y. Lapidot, and antibodies to mouse L-cell IFN by Dr G. Galasso. This work was supported by GSF (Israel) and NCRD (München).

## Transcriptional fidelity of histone genes injected into *Xenopus* oocyte nuclei

Ch. Hentschel, E. Probst & M. L. Birnstiel

Institut für Molekularbiologie II der Universität Zürich, Hönggerberg, 8093 Zürich, Switzerland

Previous work has indicated that at least some of the genetic information required for the expression of sea urchin histone genes is recognized following injection of the gene repeat (h22) into *Xenopus* oocyte nuclei<sup>1,2</sup>. The ability to elicit the expression of cloned genes and their sequence-manipulated counterparts is proving invaluable in analysing the molecular details of gene expression<sup>2,3</sup>. Direct injection of such genes into *Xenopus* oocyte nuclei remains one of the simplest methods for obtaining such expression and a remarkable degree of transcriptional fidelity has been demonstrated using this system with RNA polymerase III genes<sup>4–9</sup>, and to a lesser extent with rDNAs transcribed by RNA polymerase I<sup>10,11</sup>. In the case of polymerase II genes there is ample evidence for coupled transcription-translation<sup>12–14</sup>, but the degree of transcriptional fidelity involved may, as has recently been shown for the ovalbumin gene<sup>15</sup>, be minimal. However, clearly if the oocyte is to be used to investigate transcriptional regulation of such genes, transcriptional fidelity defined as the production of correct RNA termini, rather than the production of 'functional mRNAs' (ref. 15), must pertain<sup>16</sup>. Here we demonstrate such fidelity in the expression of all five *Psammechinus miliaris* histone genes comprising a repeat unit. However, we find large quantitative variations in the levels of synthesis of the individual correct termini and hence of the mRNAs. In addition to the mRNAs, species with no detectable counterparts in the sea urchin are generated off the coding strand, as are heterogeneous noncoding species.

We have previously shown that RNA electrophoretically indistinguishable from authentic H2A and H2B mRNAs is synthesized by polymerase II-transcribing supercoiled micro-

injected histone gene repeats<sup>1</sup>. Moreover, the histone DNA must be free of vector DNA<sup>1</sup> because its presence (both in *trans* and in *cis*) is strongly inhibitory. We have also argued that these mRNAs are essentially primary transcripts<sup>17</sup>, and thus reflect faithful transcription in the oocyte<sup>1,2</sup>. Consequently, the lack of high levels of the other mRNAs (H3, H4, H1) implied some transcriptional deficiency such as a lack of fully functional promoters for these genes with respect to the *Xenopus* enzymes. This explanation seemed most probable for the H1 and H4 genes, as they (in contrast to the H3 as well as the H2A and the H2B genes) lack clear versions of the TATAAATA and cap sequence upstream of the structural genes<sup>17</sup>.

To test this idea we needed to assay levels of correct promotion (production of 5' termini) independent of termination. We therefore cut the h22 repeat with a combination of restriction enzymes which produced fragments five of which gave suitable overlaps to all the h22 5'-mRNA termini from within the coding sequence (Fig. 1b). As the 5' termini of the mRNAs have been mapped previously<sup>17</sup>, the lengths of the overlaps could be predicted and the relative levels of the correct 5' termini in RNA samples visualized by a multi-probe 5' S<sub>1</sub> mapping technique (see Fig. 1 legend). When authentic sea urchin RNA is used with this probe, there are, as predicted, strong bands protected by the 5'-terminal sequences of the five histone mRNAs and with the anticipated sizes (Fig. 1, lane 3). Positive identification of the correspondence of bands to given mRNAs was achieved by mapping partially purified mRNAs with the multiple probe (lanes 4–8, H4, H2B, H3, H2A, H1 mRNAs, respectively). The faint high-molecular-weight bands are due to renatured DNA probe fragments whose labelled ends were not removed by S<sub>1</sub> nuclease because they co-migrate with the input DNA and are observed independently of the RNA (not shown).

These results with authentic sea urchin mRNAs may be compared with the strikingly similar pattern of protected bands observed when h22-injected oocyte RNA is used as the RNA component of the reaction (Fig. 1, lane 2). Bands corresponding to all the correct mRNA 5'-terminal sequences are present, indicating a qualitatively correct promotion of these genes but with relative intensities significantly different from those present in the sea urchin RNA. This is most evident for the H4 5' band which, although relatively very faint, is nevertheless clearly

**Fig. 1** Multiple-probe  $S_1$  mapping of h22 5' mRNA terminal sequences present in sea urchin-derived RNA or in h22-injected *Xenopus* oocyte RNA.  $S_1$  mapping was carried out essentially as described previously for individual 5' mRNA termini<sup>17</sup>, but scaled down to 10  $\mu$ l and with a 5'  $^{32}$ P-labelled, triple restriction digest (*Bam*II, *Bst*NI and *Xho*I) of the h22 repeat DNA as probe. The cognate DNA protected by the histone mRNA 5'-terminal sequences is shown in panel b. The indicated lengths of DNA protection by the individual mRNAs are calculated from previous mapping of the 5' termini and the DNA sequence<sup>17</sup>. Note that labelled 5' ends outside the mRNA map cannot be protected from  $S_1$  within a mRNA/DNA hybrid and are even susceptible in DNA duplex because they overhang the 3' termini. a, Lane 1,  $^{32}$ P-labelled DNA size marker<sup>19</sup>; lane 2, 5–14S sucrose gradient-purified h22-injected oocyte RNA from approximately two oocytes each injected with 4 ng of h22 circles and incubated overnight at 18 °C (ref. 20); lane 3, 5  $\mu$ g of total RNA from *P. miliaris* embryos at the 128-cell stage of development; lanes 4–8, partially purified *P. miliaris* histone mRNAs<sup>21</sup>, in order H4, H2B, H3, H2A and H1; lane 9, longer exposure of lane 2. Experiments in lanes 2 and 3 and 4–8 were carried out in parallel. Faint high-molecular-weight bands are due to renatured probe (see text). Numbers in parentheses indicate the size in bases.

present with longer exposure (lane 9). The H1 band is also relatively less intense than the H2B, H2A and, surprisingly, the H3 band. We interpret these differences in abundance of 5'-terminal sequences as reflecting differential promotion of the mRNA transcripts<sup>1,2,17</sup>. The alternative explanation of differential stabilities can be ruled out by our observation that the *de novo* synthesized histone mRNAs are essentially stable in the oocyte (ref. 1 and unpublished data), in apparent contrast to histone mRNAs directly injected into the oocyte cytoplasm<sup>18</sup>.

Thus, we also conclude from this experiment that differential transcription of correct histone mRNA 5'-terminal sequences in h22-injected oocyte RNA reflects the differential pattern of expression of the complete mRNAs except in the case of H3 gene, where the high levels of correct H3 5'-terminal sequences are not matched by an equal abundance of the mRNA<sup>1</sup>. A deficiency in the production of the correct 3' terminus for this mRNA, presumably as a result of poor termination, could account for this discrepancy. To test this idea and to demonstrate the fidelity in the production of 3' termini by the oocyte, we performed a multiple-probe  $S_1$  mapping similar in concept to that used for the 5' termini but with 3'-end-labelled *Xho*I/*Hpa*II fragments capable of mapping all but the H4 histone mRNA 3'

termini (Fig. 2b). The results using the sea urchin RNA or partially purified individual mRNA are shown in Fig. 2, lanes 3–9. When the h22-injected oocyte RNA is used with this probe (Fig. 2, lane 2), presumptive correct termination is indicated by strong bands corresponding to correct H1, H2A and H2B 3'-terminal sequences, but, as anticipated, only a faint band at the H3 position is observed. In fact, the H3 mRNA 3' terminus seems to be the only mRNA 3' terminus whose production is quantitatively deficient, because in a separate experiment (not shown) we detected H4 mRNA 3'-terminal sequences in an abundance which matched transcripts originating from correct H4 mRNA 5' termini. In contrast, the large imbalance of correct H3 mRNA 5' over 3' termini must be compensated by H3 RNA species with incorrect 3' termini. Further examination of Fig. 2, lane 2 suggests synthesis in the oocyte of RNA species comprising the correct H3 5'-terminal sequences but with long 3' extensions compared with the mRNA. Thus, the input *Hpa*II fragment used to probe the H3 3' region (indicated by a closed arrowhead) is protected from the  $S_1$  to a much greater extent than other input fragments, as is the next fragment transcriptionally downstream (*Hpa*II/*Xho*I; open arrowhead) which

**Fig. 2** Multiple-probe  $S_1$  mapping of the h22 3'-terminal sequences of the H2B, H3, H2A and H1 mRNAs present in sea urchin- or h22-injected oocyte RNA.  $S_1$  mapping was as in Fig. 1 legend except that the probe comprised 3'  $^{32}$ P-end-labelled *Hpa*II/*Xho*I restriction fragments of h22 as shown in panel b. The 3'-end labelling was achieved by filling in recessed 3' ends with highly purified DNA polymerase I<sup>22</sup> (from NEN nick-translation system) in the presence of [ $\alpha$ - $^{32}$ P]dCTP and using the nick-translation protocol of the supplier but without DNase addition and with a reduced incubation period (15 min at 12 °C). A low level of internal labelling nevertheless occurred, causing the background of faint, spurious band with this probe. The indicated lengths of expected DNA protection by the H2B, H3, H2A and H1 mRNA 3'-terminal sequences are calculated from previous mapping of the 3' terminal and from the DNA sequence<sup>17</sup>. a, Lane 1,  $^{32}$ P-labelled DNA size marker<sup>19</sup>; lane 2, 5–14S sucrose gradient-purified h22-injected oocyte RNA from approximately two oocytes<sup>20</sup>; lanes 3 and 9, 5  $\mu$ g of total RNA from *P. miliaris* embryos at the 128-cell stage of development; lanes 4–6, partially purified *P. miliaris* histone mRNAs in order H4, H2B, H3, H2A and H1<sup>21</sup>. Note that the H4 3'-terminal sequence is not mapped by this probe because the *Hpa*II site lies just upstream of the mRNA<sup>17</sup>. Arrowheads indicating non-mRNA-derived band in lane 2 (oocyte RNA) co-migrate with two specific input DNA fragments and are discussed in the text.

starts in the H3-H2A spacer and ends in the middle of the H2A coding region. Protection of these fragments is not apparent when sea urchin RNA is used (compare lanes 2 and 3). The exact end(s) of the H3 3' extensions cannot be unambiguously deduced from these data but the fact that one can follow specifically protected DNA fragments into the H2A coding region suggests that a significant proportion of the species starting with the correct H3 5' sequence read through to the correct H2A 3' terminus and are thus 'di-cistronic' H3/H2A mRNAs (see below). Evidence of a minor level wholly incorrect termination is revealed by the presence of discrete oocyte RNA-derived bands not present when sea urchin RNA is used (compare lanes 2 and 3).

Taken together, the  $S_1$  mapping data discussed above predict the synthesis in the injected oocyte of all five correct histone

**Fig. 3** Strand-selected transcripts of h22 in microinjected oocytes. Lane 1, overexposure of  $^{32}\text{P}$ -GTP-labelled coding strand-selected RNA transcripts of h22-injected oocytes. Lane 7 shows normal exposure. h22 strands were separated on alkaline CsCl gradients (density at  $4^\circ\text{C}$  1.700, 0.1 M NaOH, 6 mM EDTA, 30,000 r.p.m. for 3.5 days in a VT:50 rotor). Recovered single strands were judged to be about 95% pure and were bound to diazobenzylloxymethyl (DBM) paper<sup>23</sup>. Complementary injected oocyte RNA was purified by hybridization in 60% formamide, 0.15 M NaCl, 25 mM phosphate buffer, pH 7.1, and 0.2% SDS at  $45^\circ\text{C}$  for 2–12 h and elution with 90% formamide at  $60^\circ\text{C}$ . RNA was analysed on a 6% acrylamide 8 M urea gel containing 10 mM TBE buffer and 0.2% SDS, and with continuous buffer recirculation. Gels were treated with diphenylloxazole and dried before exposure. Lanes 2–6,  $^3\text{H}$ -labelled *P. miliaris* histone mRNAs<sup>21</sup> further purified with DBM filters loaded with restriction fragments comprising H2B and H3 sequences, H2A sequences, H2A and H4 sequences, H3 sequences and H1 sequences, respectively. Lane 8, noncoding strand-selected h22 transcripts obtained as for coding transcripts (lanes 1 and 7) but by hybridization to noncoding-strand on DBM paper. Note that there are several discrete 'coding' RNA species visible in this lane and similarly some polydisperse RNA is visible in the overexposed coding-strand RNA (lane 1) consistent with cross-contamination of the strands on the DBM filters accentuated by the conditions of local DNA excess in the hybridizations<sup>23</sup>. Lane 9,  $^{32}\text{P}$ -DNA size marker. The band labelled H2B\* is an example of a coding-strand RNA species whose length precludes it comprising both normal 5' and 3' termini (see text). In the hybridization conditions used for strand-selected RNA, essentially no endogenous *Xenopus* transcripts were recovered in control experiments (not shown).

mRNAs, albeit with large quantitative variations, as well as species with correct starts and stops but with readthrough at one or more termination signal (such as an H3/H2A di-cistronic transcript) and species arising from erroneous initiation and/or termination. To verify these predictions, we have analysed the h22-coded oocyte RNA from both coding and noncoding DNA strands on fully denaturing gels as shown in Fig. 3. The RNA species selected by the coding strand (Fig. 3, lane 7) are discrete and include RNA species identifiable by co-migration with authentic mRNAs (Fig. 3, lanes 2–6) as well as by hybridization (not shown) as correct histone mRNAs, with the H2A and H2B mRNAs being abundant, H1 showing an intermediary concentration and with both H3 and H4 mRNAs, whose synthesis is respectively very deficient in the production of correct 3'- and 5'-terminal sequences, being scarce but clearly visible with overexposure (lane 1). An abundant RNA species with the expected length of an H3-H2A di-cistronic mRNA (about 1,640 bases) is present, as are other species in the size range ( $\geq 1,700$  bases) expected for di- or even tri-cistronic mRNAs. The presence of an abundant di-cistronic H3-H2A mRNA explains our recent finding (ref. 1 and E.P., unpublished) that, despite the very low levels of correct H3 mRNAs, the H3 protein is synthesized in the oocyte at levels comparable to the H2A and H2B proteins. These large RNA species are not mRNA precursors because they are stable in the oocyte and exit like the mRNAs into the cytoplasm (ref. 1 and unpublished data). In addition, a minor proportion of discrete RNA species are synthesized whose length precludes the possibility that they comprise both normal 5' and 3' mRNA termini. An example is the species H2B\* which hybridizes to the H2B region of the repeat. The RNA selected by the noncoding strand (lane 8) is, in contrast, of high molecular weight and polydisperse. Although contributing a significant amount to the total mass of RNA transcripts<sup>1</sup>, it presumably arises from relatively infrequent, erroneous promotion and/or termination.

In conclusion, our results show definitely that all five genes of the sea urchin histone repeat are capable of being faithfully transcribed within an amphibian nucleus but with strikingly different efficiencies, generally reflecting the differential rates of promotion but in the case of the H3 gene reflecting defective termination. It will be interesting to know whether analogous experiments with *Strongylocentrotus purpuratus* histone genes<sup>14</sup>, or with chicken histone genes (J. Wells, personal communication) yield comparable results.

We thank Mrs S. Oberholzer and Mr F. Ochsenbein for assistance in preparing the manuscript, and K. Gross for providing partially purified mRNAs. This work was supported by a grant from the State of Zürich, by Swiss National Research Foundation grant 3.257.077 and by an EMBO fellowship for C.H.

## MATTERS ARISING

## Peridotite xenoliths in basalts and mantle dynamics

BASU<sup>1</sup> has described jointed and angular xenoliths of mantle peridotite in alkali basalts from California. He considers their morphology to be due to brittle fracture at the site where the xenoliths were incorporated into the rising magma, and thus to be representative of dynamic conditions in the upper mantle. I believe this conclusion to be unwarranted, for the following reasons.

Mitchell *et al.*<sup>2</sup> have modelled the thermal response of xenoliths to enclosing magma, and have demonstrated that blocks of the size described by Basu are heated to the temperature of their surroundings in a matter of hours. Exceptionally high magma ascent rates are, therefore, required if xenoliths are to be brought from the mantle to the surface unaffected by incorporation into basalt.

Basu assumed a newtonian rheology for alkali basalt magma when calculating nodule settling rates. This assumption is invalid as magmas commonly possess a yield strength at subliquidus temperatures. Sparks *et al.*<sup>3</sup> have considered the effect of non-newtonian rheology on the transport of xenoliths by magmas. They conclude that blocks of the sizes observed have zero settling velocity in the majority of magmas. Thus, Basu's calculation of magma ascent rate cannot be justified.

In xenolith suites where a range of rock types is represented, fragment angularity is highly variable and unrelated to mineralogy or depth of origin.

Non-newtonian magma rheology favours xenolith transport by slow, rather than rapid, ascent of magma<sup>3</sup>. Thus xenoliths are likely to have been in a state of internal chemical and mechanical disequilibrium for a considerable time before their arrival at the surface. Brittle failure occurs as a response to changing conditions after incorporation of a xenolith into rising magma. Angular ultrabasic blocks from La Palma, Canary Islands, show such clear evidence of disequilibrium as partial melting induced by heating by the host magma (my unpublished data). Ultrabasic xenoliths in basalts should be regarded as unreliable guides to dynamic conditions in the mantle.

J. A. WOLFF

Geology Department,  
Imperial College,  
London SW7 2BP, UK

BASU REPLIES—Central to Wolff's criticism is the conclusion by Sparks *et al.*<sup>1</sup> that the abundance of ultramafic xenoliths in alkalic basalts is due to the slow rates of ascent of such magmas from mantle depths. Using thermal diffusivity arguments based on such measurements in olivines, Wolff also suggests that blocks of ultramafic xenoliths will attain thermal equilibrium with their enclosing basalts in a matter of hours.

The xenoliths under discussion and other associated xenoliths in the same lava flow in San Quintin volcanic field show evidence of strong plastic deformation. My conclusion that these xenoliths could not have spent longer than a few hours in the ascending magmas is also compatible with conclusions based on recovery kinetics in deformed olivines<sup>2,3</sup>. The deformed porphyroclasts of olivine in these xenoliths are expected to be completely recrystallized in a few hours due to the relatively fast kinetics of grain growth in conditions of high temperature thermal equilibration with the host lava. The survival of the plastically deformed porphyroclasts of olivine attests to their very short-lived association with the host basalt. Thus, Wolff's contention that "brittle failure occurs as a response to (slowly) changing conditions after incorporation of a xenolith into rising magma" is untenable.

Fig. 1 Perfectly rectangular block of ultramafic xenolith in alkaalic lava from the Mt Schank volcano in SE Victoria, Australia. (Photograph courtesy of Dr Alan Moore, University of Cape Town, South Africa.)

Wolff favours a non-newtonian basalt rheology for slow xenolith transport and suggests that the "xenoliths are likely to have been in a state of internal chemical and mechanical disequilibrium for a considerable time before their arrival at the surface." Figure 1 shows an almost perfect rectangular slab of an ultramafic xenolith surrounded on all sides by the alkaalic vesicular lava from the Mt Schank volcano in SE Victoria, Australia. Could the orthogonal joint planes in Fig. 1 have

formed by brittle failure as a response to changing conditions after incorporation of this xenolith by the host magma? Or did these joint planes form before the xenolith was included in the magma? The xenolith in Fig. 1 shows typical porphyroclastic texture and evidence of plastic deformation. This evidence alone, because of the nature of the recovery kinetics as discussed above, refutes Wolff's central thesis that the joint planes formed after incorporation of the xenolith by the magma.

## Late Eocene rings around the Earth?

THE suggestion by O'Keefe<sup>1</sup> that the "terminal Eocene event" was caused by rings of tektite material encircling the Earth deserves criticism. O'Keefe assumes tektites to be of cosmic origin and cites his book<sup>2</sup> in which it is suggested that tektites originate from lunar volcanoes. This assumption is unwarranted and contrary to the numerous existing data<sup>3–6</sup>. Four specific difficulties are obvious. First, there are no known lunar rocks that are chemically suitable parent materials for tektites or which even appear possibly related to objects of this composition<sup>3–7</sup>. Second, there are no known lunar rocks of the correct age to satisfy O'Keefe's hypothesis. This is not trivial, as the most recent lunar rocks that have been dated are two orders of magnitude older than those required by O'Keefe. Third, we do not find that the North American tektites fell or were initially deposited throughout a sedimentary rock column of a few million years. Fourth, we have not found even a single tektite with a measurable cosmic ray exposure age, and the detection limits are well below the lifetime of the rings as deduced by O'Keefe.

What then caused the "terminal Eocene event?" I do not propose to answer that question. However, I do suggest that those who are interested in this problem consider the great volume of volcanic ash, air-fall tuff and bentonite (altered volcanic ash and tuff) that occurs in the late Eocene

sedimentary rocks of the Gulf Coastal Plain from Texas to Georgia<sup>8-10</sup>. Some of these tuffs and tuffaceous sedimentary rocks are similar in composition to the North American tektites<sup>9</sup> and are the probable target rocks from which the North American tektites were derived by a terrestrial impact. Thus, the terrestrial impact mechanism proposed by Urey<sup>11</sup> and others for faunal extinctions and major breaks in the geological record also should be considered, particularly in view of the recent work by Alvarez *et al.*<sup>12</sup> which supports this possibility.

If there ever were rings around the Earth, it is certain that the North American tektites (or any of the other presently known tektites) were never a cosmically derived fraction of those rings.

**O'KEEFE REPLIES**—The present issue is whether tektites are cosmic or terrestrial in origin. The main point<sup>1,2</sup> is that the terrestrial hypothesis is found to conflict with the laws of physics, and these arguments have not been answered. Two examples are given below.

First, tektites are good glasses; that is, even in decimetre-sized pieces they are homogeneous and non-porous, unlike impact glasses. The production by meteorite impact (and immediate distribution over distances of thousands of kilometres) of good glass having very low water content, starting from ordinary rocks or soil, is not possible. The diffusion coefficients are too small to permit rapid homogenization<sup>3</sup>, and the bubbles will not escape in free flight because they have no buoyancy.

Second, many tektites were obviously shaped by surface tension. Certain hollow tektites, when liquid, were so delicate that a breath (literally) would have destroyed them<sup>4</sup>. But the terrestrial origin idea demands non-isotropic launch pressures of over half a million atmospheres (50 GPa), followed by entrainment in air behind a shock wave capable, as a minimum, of blowing out the top of the atmosphere<sup>4</sup>.

As regards King's first difficulty, lunar quartz monzonites and rhyodacites having tektitic major-element composition have been reported<sup>5-7</sup>.

On his second difficulty, note that terrestrial obsidians are also largely confined to the Cenozoic<sup>8</sup>, and further that although most lunar basalts are more than 3,000 Myr in age, others<sup>9</sup> are distributed over younger ages.

The remaining two difficulties and the conclusion are invalidated by the fact, which I had mentioned, that the (dominant) solar Poynting-Robertson effect seems to move the particles outward.

I have discussed elsewhere<sup>2,10</sup> the detailed chemical arguments in King's references, and my discussion of them has not been answered. Those arguments are, in any case, merely appeals to plausibility, which should not persuade us to accept violations of physical law.

## Proposed fossil tree shrew genus *Palaeotupaia*

CHOPRA and Vasishat<sup>1</sup> described a skull fragment with partial dentition of a fossil tree shrew (family Tupaiidae) from Miocene Siwalik deposits in India. Together with a maxillary fragment and an isolated lower molar from the same locality<sup>2</sup>, and some incomplete craniodental remains from the Miocene Siwaliks of Pakistan<sup>3</sup>, these specimens provide the first documentation of the fossil history of tree shrews. No generic or specific allocation was attempted for the Pakistani fossils or for the maxillary and isolated dental remains from India.

In contrast, Chopra and Vasishat<sup>1</sup> assigned their skull fragment to the new genus and species *Palaeotupaia sivalicus*. Although acknowledging that *Palaeotupaia* closely resembles *Tupaia*, they asserted that generic distinction was warranted because of "morphological differences and the large age gap between

our specimens and the living genus". However, their only discussion of differences between the two genera was limited to enumerating several cranial and dental traits that distinguish between *Palaeotupaia* and *Tupaia minor*. All the supposed differences of *Palaeotupaia* (proportionately longer face, less posterior incisive foramina, distinct protocone on P<sup>3</sup>, more transverse P<sup>4</sup>, and divided mesostyles on upper molars) occur in some species of *Tupaia*<sup>4-6</sup>. No assessment was presented of the possible primitive or derived nature of resemblances among Siwalik fossils and extant tupaiids. Few, if any, dental traits of *Tupaia* are uniquely derived within the subfamily Tupaiinae. Although at least two derived cranial features (posterior palatal vacuities and enlarged zygomatic foramen) distinguish *Tupaia* and *Lyomgale* from other tupaiines<sup>6,7</sup>, these regions are unfortunately missing from both the Indian and Pakistani fossil skull fragments. Finally, the geological age of the Indian skull fragment is not a biological attribute and is irrelevant in evaluating its possible generic affinities. There are several extant eutherian genera whose geological history extends back to the Miocene or earlier, including the chiropteran genera *Rhinolophus*, *Hipposideros*, *Megaderma*, and *Myotis*<sup>8</sup>.

Because no essential differences in craniodental morphology which might serve to distinguish between *Tupaia* and *Palaeotupaia* were identified, it is premature to propose generic distinction for the Indian Siwalik skull fragment. Instead, the evolutionary relationship of this fossil can be expressed best by either including it questionably in the genus *Tupaia*, or, perhaps more appropriately, by stressing its essentially modern aspect while withholding generic allocation until more complete specimens are recovered, or the holotype of *Palaeotupaia* is studied more thoroughly.

13 November 1980

How to speak out on Sakharov *et al.*?

Gor'kii, where Andrei Sakharov is under house arrest, is well to the east of Moscow. Those who live there, willingly or otherwise, cannot at this time of the year forget that the long winter has begun. The sun will not shine strongly again until the best part of half a year has passed. The central isolation from which the inhabitants of Gor'kii suffer even at the best times of the year will for a long time to come be indistinguishable from desolation. Andrei Sakharov's letter (see page 112) is thus a reminder of the plight of others than himself. In some respects it may be as bad to have to live in Gor'kii because nothing else suggests itself, as to happen to live in Gor'kii because one has been taken there by force. If imprisonment is the lack of freedom, and if the sense of freedom is the sense of having chosen to live in a chosen way, many of Sakharov's fellow residents may be as deprived of liberty as he without question is. Sakharov should not blame himself if his letter prompts those who read it to remember that his problem is part of a larger problem, one that will still be with us in the spring. How could it be otherwise, in the week that the first review conference on the Helsinki accords begins in Madrid?

Sakharov makes several points, some of them particular. Plainly he is dismayed that the conference at the Hague at the beginning of September should have been based on assumptions that are incorrect. The KGB may have tried to prevent him publishing his three recent papers in English in the West, but it had no influence with the editors of *Zhurnal éksperimental'noi i teoreticheskoi fiziki*. There is no scientific library across the street, only "mud and piles of rubbish". (No doubt the snow has by now made them less unsightly.) The reason that he cannot talk to scientific colleagues is not that the others who work in Gor'kii work on classified projects but that he is prevented from going out, and from receiving visitors. (The personalized radio jamming equipment is a refinement.) There is no telephone.

Sakharov also raises more general questions. Why, he asks, is it supposed that his treatment is mild simply because he has not been sent to a labour camp? Is loss of liberty now measured on a discontinuous spectrum, with hardly anything between full citizenship and endangered life? If so, he implies, any loss of liberty is absolute. To know that the KGB can break into your flat when it chooses may be as intolerable as to know that you may be worked to death on somebody else's whim. Naturally he is sorry for his friends and fellow-scientists — Orlov, Shcharanskii, Velikanova, Nekipelov, Lavut, Ternovskii, Osipova and the rest. The severity of their plight does not make his own supportable.

**Imprisonment without trial**

Then, he asks, what happens when a person's loss of liberty comes about because a government has assumed the right to break its own laws? The constitution of the Soviet Union resembles that of other modern states in its assurance that people will not be deprived of liberty without due process, usually a trial by a court. So, Sakharov asks, how has the word got about that it can be in his interest not to make too much fuss outside the Soviet Union in the hope that the authorities will then quietly relent and let their illicitly imprisoned prisoner return to Moscow? What Sakharov wants, he says, is due process — a formal charge, a fair trial and either a fair sentence or a discharge.

Sakharov appears not to appreciate the enormity of his demand. The Russians (which is not necessarily a synonym for "the Soviets") have had a flair in the past few centuries for mingling tyranny with essays at rebellion. The one, of course, provokes the other. Tolstói might have been as complacent as his fellow-landowners if the feudal state of the nineteenth century

had been less repressive. Dostoevskii might have consented to entertain the middle classes with popular romances if only there had been more romance to brood about. Sakharov is one of the many who, in the past few years, have dug in their heels and insisted on the rule of law and the validity of international agreements such as the Helsinki accords. By doing so, he runs great risks for himself and his family. Forced emigration would solve nothing, but would be the ultimate humiliation. Sakharov's plight is haunting.

What, if anything, can be done to help? Sakharov's letter provides some clues. He is concerned about his relatives and about his son's fiancée. Experience in the past few years has shown that it may sometimes help if the names of those threatened with trouble of some kind are well known outside the Soviet Union. But publicity is not a certain remedy, as the cases of the Orlovs of that world demonstrate. Perhaps the best that can be offered is the occasional message of good cheer, perhaps even a reprint of a scientific paper that might interest him. It is sad that there is so little else to offer, with the winter setting in at Gor'kii.

But is this not an issue on which the interests of the scientific community as a whole should be engaged? The question is unfortunately more complicated than it seems. Sakharov may be a member of the scientific community, but he is also a citizen of the Soviet Union, and his disagreement with his government is about civil liberties, not scientific issues. To what extent, in these circumstances, is the scientific community entitled to be engaged?

**Constraints on protest**

To a first approximation the answer is that the international scientific community has no special duty to protest at what is happening to Sakharov and those of his fellow scientists who are formally imprisoned. The Soviet Union has a constitution which guarantees due process, but also a criminal code which arranges that people are brought to trial for reasons that are elsewhere unacceptable. The trouble is that the scientific community as such has no special competence in persuading national governments to follow seemingly legal practices. And even where Soviet citizens such as Sakharov have been harmed outside the law, by being deprived of jobs or deprived of liberty without even an unfair trial, to a first approximation the issue is not one for the scientific community. Others than scientists are dealt with in such ways. Injustice, it appears, is impartial. This is why, in the past several years, the problems of those such as Sakharov have been such a rich source of frustration for their colleagues elsewhere.

The second approximation, fortunately, offers a little more hope, and for two reasons. Scientists are fond of saying that science is international and that the scientific community is inherently more interdependent than other communities of scholarly or professional people. Too much is often made of these propositions, which, nevertheless, contain a germ of truth. We are all the losers if people like Sakharov cannot work as effectively as they might, and talk as freely as they would wish about what they have done. Ironically, the past few decades have demonstrated the eagerness of even the Soviet government to make formal arrangements for the movement of Soviet scientists in and out of the Soviet Union.

The second chink of hope is that the Helsinki accords exist. They are not a formal international convention, but a declaration of intent. The declared intention is liberal, if only vaguely so. People are to be free to move from one country to another if they wish, free to correspond with colleagues elsewhere, free to do a variety of things now often denied. The objective of the

conference opening this week in Madrid is to assess progress and to decide what should next be done. The outcome will not carry the Helsinki accords much further. The most immediate danger is that such hard things will be said that the process of relaxation will be set back. Yet the accords provide a licence for scientists outside the Soviet Union to speak their minds from time to time.

This is the spirit in which more than 270 distinguished scientists bought advertisement space in the London *Times* last week asking for the release of fellow scientists now locked up. Lord Todd, the President of the Royal Society, followed this on Friday with a letter in *The Times* asking that the British government should make an issue with the Soviets about Sakharov, Orlov, Shcharanskii and the rest. These developments are creditable. The US National Academy of Sciences declared itself to the same effect more than a year ago. But it is important that the scientific community in the West should clearly appreciate what it is about with such declarations. Because of its connections, because science is indeed international, it happens to have learned of some appalling injustice. But classicists, farmers and lorry drivers are similarly deprived of liberty without good cause. The scientific community must appreciate that by asking that Western governments should do what they can to persuade the Soviet government to change its ways, it is asking a political and not a scientific favour. The scientific community is entirely within its rights to do so. Science will continue to be diminished if the Soviet contribution is inhibited by illiberality. The knowledge that protest is bound to be understood as political protest has no doubt helped to keep the scientific community silent all these years. To urge governments to take up cudgels is the proper course.

### No boycott

Talk of boycotting relations with Soviet scientists is, however, mistaken. In the past few weeks, Sir Brian Pippard and others have been drumming up support for a temporary boycott. Scientists in the West, they say, should not receive Soviet scientists in their laboratories and should not attend conferences in the Soviet Union until the diplomatic conference in Madrid is over. The argument would make sense if there were reasons to suppose that a boycott would succeed in influencing what happens at Madrid. The chances of that are small.

Although there will be many in the West who will now follow their individual inclinations and boycott Soviet science, it will be best if those not that way inclined can try to strengthen relationships with their Soviet colleagues, at the same time leaving them in no doubt of how the illiberality of the Soviet state offends the consciences of others and impedes the advancement of science as well. Soviet colleagues should be welcomed, if anything more warmly than in the past, but also spoken to more openly than has been the custom. The genteel convention that one does not embarrass a visitor by talking politics is now outmoded. For the best but cruel hope for Sakharov and his like is that there should be more of them.

In following such a line stridency must be avoided. A sense of perspective is essential. It is thus relevant that what the Soviet government has done to Sakharov *et al.* does not hold a candle to, say, what Pol Pot did in Cambodia between 1976 and 1978. Moreover, the West cannot be too smug in its complaints against the Soviet way of dealing with people such as Sakharov — it is after all only a quarter of a century since Senator Joseph McCarthy was riding high in the United States administering injustice in an arbitrary way. Russian illiberality is, however, a special challenge because the Russian state is within an ace of being decent. Personal freedom is guaranteed by the constitution. The Soviet educational system, much admired elsewhere, creates expectations of freedom. The industrial development of the past half century depends on the involvement of trained people in a variety of occupations, technical and managerial, that are efficiently carried out only when people are free to move about within the system and free to contribute to industrial development in ways that best suit individual talents. Is it too much to hope that some future Soviet government will recognize that economic and industrial stagnation is too high a price to pay for the right to lock

people up on flimsy charges?

The revolution, ostensibly directed at Tsarist feudalism, seems not have touched what is the essence of feudalism — the notion that people's lives belong in their entirety to the state. This is the basis on which it is supposed that ordinary unrebelling people in the Soviet Union should have less freedom than is habitual elsewhere to choose what they work at and where they live. The institution of the collective farm is not very different from that of the mediaeval *desmesne*, while the recent understanding that members of the collectives should be allowed to work some land on their own account is the Soviet analogue of the mediaeval practice of granting the right to work strips of land in a common field to the dutiful dependants of a manor.

Experience of the Dark Ages in Western Europe shows clearly enough that in such a feudal system the lack of freedom is not absolute and the condition of society not entirely static. Just as, in mediaeval society, bright young people escaped from the villages in which they were brought up by joining some influential religious order and moving on a wider stage, so in the Soviet Union there is a constant and substantial flux of young bright people through the special schools and through the universities into the professions, the scientific professions among them. For other people, it also helps that the modern equivalents of the lords of the manor — the local party bosses — are susceptible to influence: a person may reasonably expect to improve the lot of himself and his family and never get into trouble provided he is willing never to ask for what may be forbidden. For every Sakharov, there may be 100,000 content to live within the system. The course of events will be determined not by the number of open rebels but by the unknown influence of those with similar inclinations still undeclared.

So does it follow that Sakharov and his fellows in adversity have no choice but to wait for a counter-revolution? That gloomy logic is fortunately unsound. Although the feudal practices of the Soviet government have the obvious advantage of keeping the government of the day in power, there is no reason to suppose that they are essential to the survival of socialism, communism, Marxism or whatever blend of those ingredients may be fashionable. To be sure, it is a depressing truth about the past half century that most communist governments have kept their ideology intact by restricting liberty, if only at the margin. The fate of Mr Michael Manley's government in last month's elections in Jamaica will no doubt reinforce them in their prejudices. Yet is it not ironical that many of those who find themselves in Sakharov's plight are as concerned with the survival of the Marxist state as are their governments? Liberty need not spell the end of the Revolution even though each year that passes makes the conflict between them sharper.

### No choice

So what is to be done? The wisest assumption is that nothing much will change: that Madrid will be a disappointment but that the Helsinki accords will remain in being; that Mr Reagan's government in the new year will reopen discussions about arms limitation but will not embrace detente with much enthusiasm; that Soviet troops will stay indefinitely in Afghanistan but will not take day t day charge in Poland; and that Soviet scientists will not be free to travel overseas. Western governments at Madrid will no doubt make the best they can of what the scientific community has been asking of them in the past few months, but are likely afterwards to be preoccupied with other things. The scientific community will then be left to its own devices, which are primitive yet potentially effective. The objective must be to strengthen, and not let lapse, the recent pathetic trickle of intercourse with Soviet scientists on scientific matters in the hope that there will be a growing company of Soviet scientists prepared to acknowledge the value of liberty. It sounds an insubstantial remedy, yet the scientific enterprise is more robustly international in character than other branches of scholarship. The scientific community is now challenged to show that its faith in this principle can be upheld. And that is the best hope that Sakharov will not still be living against his will in Gor'kii for many winters to come.

# Reagan's election cheering for science?

## Harder line promises more spin-off funds

### Washington

A big step for US politics, but a relatively small step for US science seems to be the main verdict on last week's presidential and congressional elections, with scientists unlikely to suffer as much from a swing to the right as other recipients of government spending.

President-elect Ronald Reagan has already said that he wants a 2 per cent across-the-board cut in the budgets of all federal agencies next year. But he is on record as supporting increased funds for research and development, a larger defence budget (with its spill-over into basic research) and the retention of both the Office of Science and Technology Policy (OSTP) and the post of President's Science Advisor.

The Republican takeover in the Senate has been as significant as Reagan's victory. The defeat of a significant handful of liberal Democrats will mean a major shift in the content of legislation. Again, however, the science budget may escape serious cuts, partly because key committee positions are likely to be filled by liberal Republicans, such as Senator Charles Mathias of Maryland, who have long been supporters of increased research funding.

Although little was said about science during the presidential election campaign, Mr Reagan has made it known in the past few weeks that he favours increased spending on science, particularly in areas related to defence needs. His main publicly-stated reservations were about the organization of OSTP, whose new staff would, he said, gather information in an informal way "rather than relying on 'blue ribbon panels' which are often partisan and work in secret".

The key question is who will fill the major science and technology positions in the new Reagan administration. Many of these choices are unlikely to be made until the new year. But preliminary discussions were held last weekend by a task force whose members indicate the likely directions of a Reagan science policy.

The task force was brought together by Dr Simon Ramo, co-founder of the advanced engineering firm TRW Inc., an adviser to Mr Reagan during the election campaign and former chairman of a congressionally-established federal science and technology committee under President Ford.

Co-chairman of the task force is Dr Arthur Bueche, vice-president of research and development for the General Electric

Company, a strong supporter of nuclear power and a possible Science Advisor.

Other members of the task force include Dr Harold Agnew, past director of the Los Alamos Scientific Laboratory; Dr Ed David, president of Exxon Research and, for a time, President Nixon's Science Advisor; Dr Frederick Seitz; Dr Guy Stever, ex-director of the National Science Foundation (NSF) and President Ford's Science Advisor; Dr Bill Baker, past president of Bell Laboratories; and Dr Edward Teller, a close adviser to Mr Reagan when he was governor of California.

Also included are several senior administrators from the defence and aerospace industries, including Dr Albert D. Whelan, vice-president of the Hughes

Aircraft Corporation and a strong supporter of the commercialization through private industry of communications and Earth monitoring satellites.

One immediate task for the committee is to select a new administrator for the National Aeronautics and Space Administration (NASA) to succeed Dr Robert Frosch, who has already announced his intention to take up the position of president of the new National Association of Engineering Societies in January.

Less certain is whether an immediate successor will be sought for Donald Dr Fredrickson, director of the National Institutes of Health. Dr Fredrickson was

## Plusses and minuses, election 1980

### Plus

**Fast breeder research.** One of Mr Reagan's first actions as President is likely to be to lift the embargo on the construction of the Liquid Metal Fast Breeder Reactor at Clinch River in Tennessee. Most of the major components have been built, but the test reactor's completion was held up by President Carter because of proliferation dangers and also a belief that fast breeder reactors are unlikely to be needed in the United States until well into the next century. Utility companies, however, which have provided a substantial amount of the funds, are keen to see the project completed, and are now likely to get their way.

**Chemical weapons.** President-elect Mr Reagan is also likely to give the go-ahead to a new facility for producing binary chemical weapons, favoured in Congress but, following President Nixon's earlier ban on their production, requiring a presidential declaration that such weapons are needed. In a campaign statement, Mr Reagan said that since binary weapons are much safer to stockpile and transport than existing stockpiles of poison gas, "we should proceed with preparation to convert to binary weapons".

**Science court.** In another statement, Reagan also said that he would explore the feasibility of a "science court" to help arrange public discussions of controversial scientific issues, a proposal that generated considerable publicity four years ago, but has since lapsed into relative obscurity.

**House of Representatives.** The House has lost one of its three scientist members, Mr Mike McCormack (see below), but has gained another, Mr Jim Coyne, an energy analyst and president of the Coyne Chemical Corporation. With Mr Coyne's election, all three scientists in the House are now Republican.

### Minus

**Mr Mike McCormack,** previously chairman of the House Science and Technology Committee's powerful energy research subcommittee, a strong advocate of nuclear power and a leading architect of recent nuclear fusion research legislation. Mr McCormack lost a tight race in Washington, where his district included the Department of Energy's Hanford Reservation.

**Mr Jerome A. Ambro.** A Democrat from Long Island, Mr Ambro was chairman of the Science and Technology Committee's subcommittee on natural resources and environment. He played a significant role in generating congressional approval for the 400-GeV particle accelerator, ISABELLE, at the Brookhaven National Laboratory.

**Environmental regulation.** The loss of liberals such as Senators Frank Church (Idaho), John Culver (Iowa) and Gaylord Nelson (Wisconsin) and Representatives Bob Eckardt (Texas) and Andrew Maguire (New Jersey) will be a major blow to supporters of tough environmental regulation. Their only consolation is the re-election of another liberal, Congressman Morris Udall, chairman of the House Interior Committee. Mr Reagan has promised to repeal environmental and health legislation that is considered unnecessarily burdensome to industry.

**Alfred Carnesale.** The change in administration makes it unlikely that, as proposed by Mr Carter, Dr Alfred Carnesale, professor of public policy at Harvard's Kennedy School of Management, will now become chairman of the Nuclear Regulatory Commission. Although respected as a negotiator, Dr Carnesale is closely identified with a Ford-Mitre study that strongly influenced President Carter's stand against fast breeders.

**David Dickson**

initially appointed by President Ford and was retained by President Carter; he had previously indicated that, even if Carter won, he would probably leave some time next year.

At NSF, although the Senate has approved the nomination of Dr John Slaughter as the new director, he has yet to be sworn in by the President and it is possible that Mr Reagan will wish to propose another candidate for what is supposed to be a relatively non-partisan appointment.

In the Senate, much will depend on how the chairmanships of the various committees are allocated. One of the most prominent election casualties was Senator Warren Magnusen, long-time representative of the state of Washington, who as chairman of both the Senate Appropriations Committee and its health subcommittee had presided over a period of substantially increased funds for biomedical research.

If the Democrats had retained control, the subcommittee chairmanship could have passed to Mr William Proxmire, the scourge of NSF. As ranking Republican, however, the position could now be taken by Senator Mathias — unless he prefers to take over Mr Proxmire's committee, which is responsible for the budgets of both NSF and NASA.

NASA's hopes for a relatively sympathetic hearing in the Senate have also been raised by the likelihood that the chairmanship of the Commerce Committee's science, technology and space committee will pass to Republican Senator and former astronaut Jack Schmitt, a keen supporter of the space programme and of increased funds for space science.

In the House of Representatives, which remains in the hands of the Democrats, the main changes will result from a possible reorganization of the Science and Technology Committee, where three subcommittee chairmen — Mr Mike McCormack, Mr Jerome Ambro and Mr John Lloyd — all lost their seats.

David Dickson

## Polish unions

## Science not lost

### Gdańsk

In spite of the legal wrangles over registration and the need to prepare contingency plans for a possible nationwide protest strike, Poland's new independent self-governing trade union, *Solidarność*, has already started work. Among other things, it established, at the end of last month, its All-Poland Coordinating Commission for Science.

This at first glance is somewhat surprising, because the present policy of *Solidarność*, as the very name implies, is to build a strong union organization without subdivisions by trade or profession. Profession-based branches were originally

planned for a later stage. Such a policy meets with the aspirations of the many briefly established new unions which, after the creation of *Solidarność* in mid-September, were quick to amalgamate with it. As Dr Zdzisław Bibrowski, erstwhile chairman of the Independent Trade Union of Scientific, Technical and Educational Workers (founded 8 September — see *Nature* 18 September — merged with *Solidarność* 13 October) explained, the members felt that in the present fluid situation they needed greater bargaining power and protection than a single small union could afford.

The *Solidarność* commission for science is not intended to be a separate interest group but rather a working party to elaborate the union's practical suggestions on the strengthening and renewal of the role of science in Poland.

Such a renewal is widely accepted as a major factor in getting the Polish economy out of its present crisis. It was the theme of last month's extraordinary General Assembly of the Polish Academy of Sciences and of a number of statements by academic and scientific bodies throughout the country. Lech Walesa, the leader of

*Solidarność*, told me last week "Speeches and declarations are not the point. We need concrete activity."

Such activity will be the role of the *Solidarność* commission. As Dr Wojciech Gruszecki, a chemistry lecturer at the Gdańsk Technical University and the *Solidarność* spokesman on science and technology explained, the commission, which has already met several times in Poland's leading academic centres (Krakow, Warsaw, Gdańsk, Wrocław) hopes to work out some concrete proposals and submit them to the government; so too during the next few months will the Academy of Sciences and the country's various learned bodies. New legislation on science in Poland is now being drafted and will shortly be presented to the Sejm (parliament). In the current atmosphere of greater "openness" a lively public debate is expected.

On many points, including the need for greater autonomy in academic life and the lifting of censorship restrictions, the scientific and academic community is unanimous. *Solidarność*, however, would go further. As Dr Gruszecki explained, the union urges that science be treated as a non-

## University of Warsaw changes course

### Warsaw

The expected liberalization of Polish academic life is not entirely a consequence of the Gdańsk accords, according to a spokesman for the Polish Ministry of Higher Education and Science. Rather, he said, it is the culmination of a continuing process. Thus the promise of a greater degree of self-government for the universities was already foreseen in guidelines drawn up several months ago.

The ministry, it appears, wishes to seem well abreast of developments. This has been especially the case since the surprise resignation at the end of September of the rector of Warsaw University. With widespread talk of academic autonomy, the ministry found it prudent to offer a compromise solution for the appointment of his successor. It proposed a list of three candidates, from whom the university senate made its final selection.

The senate is now committed to the principle of academic autonomy. The pro-rector, Dr Kazimierz Dobrowolski, stresses that the university should be able to draw up its own syllabuses and courses. Even under the present system, he says, some latitude is possible. In his own subject, biology, the university has been able to initiate courses in such new fields as environmental biology and molecular genetics. The result, he says, is that no student can graduate with simply a nineteenth century knowledge of biology.

The academic staff at the university is

nevertheless concerned with falling standards among candidates for entry. The educational reform, introduced three years ago, which replaced the traditional eight years of primary schooling and four years lyceum by a comprehensive ten-year schooling, alarmed both parents and university staff. Although three years is strictly too short a time in which to assess the new system, the Ministry of Education has been quick to read the signs. Although no official announcement has yet been made, a recent article in the weekly *Perspektywy* suggests that the new Minister of Education, Krzysztof Kruszewski, intends to revert to the former system, with certain changes in syllabus incorporated from the ill-fated ten-year system.

A recent development at Warsaw University has been the inauguration of a course of Friday evening lectures by members of the Society for Academic Courses (the "Flying University") whose aim is to fill the gaps left by the state system of instruction. The lectures, held in the Adam Mickiewicz Hall (the largest lecture room in the university) are not, however, formally sponsored by the Society for Academic Courses. The hall is leased to the new Independent Students' Union, which invited the speakers. But, as one of the student organizers said, the correspondence between the list of lecturers in the Mickiewicz Hall and the members of the Society for Academic Courses is hardly coincidental.

Vera Rich

commercial activity and financed by a budget which would ensure the total autonomy and freedom of scientific research. Research, he said, should not be "cramped" by government plans. Industrial research should be carried out in the research institutes of the ministries concerned (a network of such institutes does exist), or contracted out to academic institutes; but the overall direction of research by the government should cease.

In effect, Solidarność is seeking a major change in Poland's science policy. Since the early 1970s, research has been organized and funded on the basis of a complex hierarchy of "problems" (governmental, key, interdepartmental, departmental and branch problems) geared to the needs of the national economy. Research on a given problem will generally be carried out at many institutes simultaneously, and problems of coordination and control, including the interface between the academic and governmental sides, have led to a proliferation of bureaucracy. The establishment view, however, as represented by Dr Ignacy Malecki, director of the Institute of Fundamental Problems of Technology of the Polish Academy of Sciences, is that the problem structure is not in itself a bad thing. Dr Malecki, a member of a special commission looking into the management of the "problem" system, said that the consensus was that the system should stay, although trimmed of its bureaucracy. He added that in his opinion there was room for improvement in financing. **Vera Rich**

## Science council

### Mess about money

The UK Science Research Council is in a financial mess. But nobody can say how serious the trouble is, because figures and tables released in the 1979-80 annual report last week are wrong. The SRC now confirms the misuse of a computer program, as a result of which some research grants which have ceased have been displayed as current. A claim in the report that grant payments had increased by 72 per cent since the previous year took SRC officials four working days to disown once the inconsistencies had been pointed out to them.

Behind this is a more serious problem — what chairman Sir Geoffrey Allen last week called a "hiccup" in the council's cash flow. He and his officials are being coy about the size of this financial spasm. Some say that the council must find at least £10 million from within its current budget to pay for excesses last year in grant-giving by the Science Board, responsible for small science and neutron and synchrotron radiation physics, thus shedding doubt on claims earlier this year that the Science Board was turning away "alpha quality" grant applications for lack of cash.

The anomaly dates back to a success:

### Hardship everywhere

The Science Research Council's report for 1979-80 (HMSO, £7.10) is liberally spattered with references to the consequences of financial stringency, within a budget totalling £176 million. The budget last decreased 1 per cent in real terms in 1980-81, and will show a modest increase after that — but, says the report, new initiatives will be impossible without producing stagnation in favoured areas of the council's programme, or markedly reducing other programmes.

**Nuclear physics** is the most vulnerable of the big spenders — although contributions to CERN fell from £27.7 million in 1978-79 to £25.3 million in 1979-80 largely because of the stronger pound. The nuclear physics budget is not one of the "favoured areas" of the SRC's programme, and it has fallen a factor of two in real terms since 1975-76. It will fall again by 18 per cent this year, and another 9 per cent the year after, says the report, to £2 million below a "minimum programme"; but despite this the board sees LEP, the large electron positron ring that CERN plan, as its accelerator for the late 1980s, as its highest priority. It is "seeking council support" on this project. Meanwhile, equipment for the 30 MV Van de Graaff Nuclear Structure Facility under construction at Daresbury is to be further delayed.

**X-rays and neutrons** provided by the synchrotron radiation source at Daresbury, opened last week, and the Spallation Neutron Source under construction at the Rutherford Laboratory are threatened by lack of money to exploit them; and existing neutron sources will be run down. The high proportion of the Science Board's funds devoted to neutron scattering will fall after 1981-82, when the modernization programme at the Institut Laue-Langevin high flux reactor at Grenoble, in which the UK is a partner, is completed.

**Computers.** The SRC needs to find £8 million capital "over the next few years" to replace its central computers, and more if allowance is to be made for an increasing demand.

**Research students** supported by the SRC will continue to be a falling proportion of good graduates in science or engineering. In 1972, 46 per cent of such graduates, applying for SRC grants, were awarded them. In 1979-80 the proportion was 36 per cent, and now the number of grants must be held constant against an increase — for the next few years — of about 4 per cent a year in university output. But there should be a few more cooperative awards in science and education (CASE awards), designed to link students with industry as well as university. Even so, this council hopes to fund more in-service training.

**Robert Walgate**

that of Mrs Shirley Williams, Secretary of State for Education and Science in the last government, in convincing her Cabinet colleagues that Britain should spend more on science. Uniquely, she brought in research council heads to convince other ministers that basic science was important — and in late 1978 won another £47 million for the councils, of which SRC would have received £33 million, payable from 1979-80 to 1982-83. Then came the new government; spending cuts, announced in the budget of June 1979, lopped off most of Mrs Williams's gift.

But well before the election she had privately warned the council chairmen to beware of Tory zeal. In case the government changed, she hinted, it would be wise to spend the money soon. In April 1979, SRC sent out a circular requesting applications for grants to buy equipment. £37 million of applications flooded in; SRC panels thought £20 million of them were deserving, and committed themselves to £7.5 million. In the event, the council received only £5 million of the Williams money.

The flood of applications, however, continued, and not just for equipment. The universities had seen the tap turned on after years of drought. It was against this background that "alpha quality" applications had to be turned down. Even so, the boards over-committed themselves and now all are being asked to cut back by delaying grant renewals.

Other factors worsen the SRC's current financial picture. Universities are putting in their bills earlier than usual, because they too have cash flow problems; and the largest price of SRC construction work — the spallation neutron source at the Rutherford laboratory — is going ahead on time (the council had allowed for slippage).

The only light comes from the strong pound, which reduced the council's subscriptions — totalling £42 million a year — to international bodies such as the European centre for subnuclear physics (CERN) and the European Space Agency by about £7 million; and from the volcanic rock underneath the new Isaac Newton telescope house at La Palma in the Canaries. Engineers had overestimated the strength of the rock, and the foundations must be rebuilt, causing a six-month delay and pushing a £500,000 bill into next year.

**Robert Walgate**

## Large space telescope

### Delay means money

*Washington*

US astronomers have successfully persuaded the National Aeronautics and Space Administration (NASA) to request additional funds in next year's budget to ensure the successful development of scientific instruments due to fly on the space telescope.

Previously, scientists had complained

that significant cost and schedule overruns with the 2.4-metre telescope, whose planned 1984 launch from the space shuttle will probably have to be postponed for up to a year, were leading the agency to cut corners in developing and testing the instrumentation thus prejudicing some of the scientific experiments.

For example, no reserve funds to meet unexpected difficulties had been included in the budget of the Goddard Space Flight Center, which is responsible for the development of the scientific instruments which will be located at the telescope's focal plane.

Partly as a result of this delay, caused chiefly by greater than expected technical difficulties in various parts of the project, cost overruns could amount to \$50–\$100 million, compared with an initial estimate of \$435–\$470 million.

The space telescope is only one of a growing list of NASA projects in the same trouble. In some cases, such as the Galileo mission to Jupiter, and the solar polar mission — delayed two years — these have been the direct result of problems with the space shuttle itself.

## Ariane sells three

*Washington*

Intelsat — the international telecommunications satellite organization — has given a major boost to European space efforts with its decision to launch three of its nine satellite global communication systems from the French-built Ariane rocket.

Intelsat had originally hoped to launch the satellites from the National Aeronautics and Space Administration (NASA)'s space shuttle. Delays in the shuttle development programme, however, have caused concern about whether the launcher will be available in time. (Even after the first launch next year, it is uncertain whether NASA will be able to keep up its promised schedule of launches.)

Ariane is also experiencing problems, and following the failure of a test flight earlier this year there is no guarantee that it will be available for the Intelsat launches, which would be the sixth, seventh and eighth in the nine-satellite, \$300 million system. In this case, Intelsat would use Atlas Centaur rockets, which because of the shuttle delays are already being used for the first five satellite launches, with the first launch due to take place next month.

The launch vehicle for the final satellite in the series has not yet been decided, because Centaur launches are likely to be considerably more expensive than the shuttle. When all satellites are in orbit, the system will double the number of international telephone calls and television transmissions that can be handled simultaneously.

**David Dickson**

But in the case of the space telescope, there have been separate problems with each of the three parts of the project: the scientific instrumentation, the optical telescope assembly and the support system module.

In the case of the scientific instrumentation there have been what one scientist describes as a not unusual set of technical problems, extra costs caused by delays and a few "minor screw-ups" in all instruments except the high-speed photometer.

It is a similar story with Perkin-Elmer, which was awarded a \$58.5 million contract for the optical telescope assembly and which has also had difficulty in keeping work on schedule, finding that it lacked sufficient manpower for design needs and that a computer-controlled method for grinding one of the two optical mirrors was not as successful as had been hoped.

More recently, the other main contractor, Lockheed, awarded a \$73 million contract for the support systems module, reported that revised cost estimates were substantially larger than those originally submitted.

Both NASA officials and staff members of the relevant congressional oversight committees are looking closely for the reasons behind the delays. In particular, Congress wants to know whether tight limits on personnel have reduced the agency's ability to review contracts awarded to private companies.

In Europe, where several companies are working on apparatus to be included on the telescope, a delayed launch will relieve pressure on schedules that were said to be getting tight.

The delay seems unlikely, however, to have a significant impact on plans for a space telescope institute, which will be responsible for analysing the data received from the telescope.

NASA is expected to announce within the next few weeks the site that it has selected for the institute. Of the original four proposals submitted earlier this year, two remain in the running. One is from the Association of Universities for Research in Astronomy (AURA), which proposes building the institute at Johns Hopkins University in Baltimore; the other is a proposal from Associated Universities Inc. to locate the institute at Princeton University.

Although both proposals are accepted by astronomers as having strong merits, the balance may have been swung in favour of Princeton by a recent federal indictment against Computer Sciences Corporation (CSC). This company, which AURA intended to use to help develop the software for handling telescope data, is being indicted on charge of fraud and racketeering arising from a 1972 time-sharing contract.

AURA officials pointed out last week, however, that the section of CSC which has

been indicted is completely separate from that which would help operate their proposed space telescope institute, and hope that this will insulate them from any action which the federal government might take against the company. The General Services Administration (GSA), against which the frauds are said to have been carried out, has suspended the company from acquiring new business from the agency until a trial which is expected to open in January. The action by the GSA could affect 200 federal users of CSC's Infonet time-sharing system.

**David Dickson**

## Biotechnology

### Celltech set up

The formation of Celltech Limited, the first British company predominantly concerned with the exploitation of biotechnology, was completed on 6 November, according to an announcement earlier this week from the National Enterprise Board (NEB), the public corporation supported with public funds. The board will be the largest shareholder in the company, with 44 per cent of the shares. The remainder of the equity will be divided equally between the four remaining shareholders, the Prudential Assurance Company, the Midland Bank, British and Commonwealth Shipping and TDC (a venture capital investment trust, itself an offshoot of Finance for Industry, a joint venture between the clearing banks and the British government).

The shareholders have already subscribed the first tranche of the £12 million that will serve as the initial capital base of the company. The board of the company will chiefly be representative of the principal shareholders, with Mr G. Jackson of Philips Electronics Limited nominated by the National Enterprise Board (NEB), but will also include Dr J. L. Gowans, the secretary of the Medical Research Council, and Sir Michael Stoker, until recently director of the Imperial Cancer Research Fund Laboratories and foreign secretary of the Royal Society. Sir Michael will also be the chairman of the company's advisory board, to be known as the Science Council.

The council will also have as a member Dr Sydney Brenner, director of the MRC Laboratory for Molecular Biology at Cambridge, who has been involved with the planning of Celltech from the beginning. Other members of the council are to be announced in the near future.

Apart from the managing director of the company, Mr S. Fairtlough, the director of research and development will be Dr N. Carey, at present director of research at G. D. Searle Limited. Dr Caroline Vaughn, like Mr Fairtlough at present on the staff of the board, will be director of marketing. Other members of the staff of the company have yet to be appointed. The chairman of the company will be Mr Wynn Denman, a

director of British and Commonwealth Shipping.

The announcement of the setting up of the new company said that Celltech has reached an agreement with the Medical Research Council (MRC) that provides a "framework" within which the company will have access to research carried out in the council's laboratories. It has also come to an arrangement with the National Research Development Corporation, the public corporation which is the principal repository of patent rights arising from research carried out in university and public laboratories in the United Kingdom. Plainly the negotiation of these agreements, no details of which have been made public, has taken up some of the time that has elapsed since the Celltech project was first announced nearly four months ago (see *Nature* 24 July).

### Veal hormones

## Total ban proposed

### Brussels

The Commission of the European Economic (EEC) has lost no time in taking steps to ban the use of all natural and artificial hormones in livestock — a draft regulation is due to come into effect on 1 January 1981. At the Council of EEC Agricultural Ministers on 30 September the Commission promised to respond speedily to a request to draw up proposals on the use of hormones and anabolic steroids. This week's Agricultural Council meeting on 10 and 11 November was to be given an account of the Commission's proposals, but will hardly have had a chance to digest them.

Although the ministers have committed themselves to speedy action there are several hurdles ahead of them. The proposals are far reaching — covering all meats intended for human consumption (veal, pork, beef and fowl). The only exception is for the use of natural hormones in therapeutic treatment, which must be carried out under strict supervision. Furthermore, the marketing of animals or carcasses containing residues above a certain level (yet to be specified) will also be prohibited.

None of this will be easy to enforce. The commission still has to devise a foolproof way of controlling the supply of hormones to vets, ways of monitoring animals from the farm to the abattoir, and ways of checking meat on retail sale. These controls are bound to involve a system of identification so that the animal's origin can be traced if the regulations are broken.

The commission's proposals will be particularly welcome in Italy, where in September a magistrate imposed a nationwide ban on veal sales and the sale of twenty-two brands of baby foods containing veal was suspended. The British position is one of traditional restraint, partly due to unwillingness to yield too

much power to Brussels and partly due to scepticism over the implementation of EEC regulations. This scepticism is shared in Germany, where laws on the import of meats have already been tightened.

Jasper Becker

### Medical research

## Born-again basics

The UK Medical Research Council (MRC) and the departments of health in London and Edinburgh are making a valiant effort to defend the transfer of Rothschild contract research monies back to the control of the MRC (*Nature* 23 October, p.669). Last week, on the publication of the MRC annual report for 1979-80, MRC secretary Dr J.L. Gowans said that his council is expected to double its commitment to "health services research" in the next five years. And Professor Arthur Buller, Chief Scientist at the Department of Health and Social Security, said that his department had pressed the MRC into the deal, rather than the other way about.

The doubling of health services research is said to be the MRC price for gaining control of the £13.85 million per annum of Rothschild cash. Since 1972 and the adoption of the Rothschild customer-contractor principle, these funds have been controlled by the health departments but spent by MRC. Under a concordat reached in 1973 between the departments and the MRC they were spent exclusively on biomedical research. Each year the departments defined their interests in a voluminous report under headings such as "blood", "mental illness", "cancer and infections" and so on; and MRC responded, detailing exactly how its biomedical research was relevant. Each year, the health departments passed the Rothschild allocation to MRC, duly increased for inflation.

Health services research, which involves social and economic as well as medical matters (for example, does amniocentesis yield a net benefit?) was, strangely, not covered by the 1973 concordat — so that the £2 million or so a year of health services research at present undertaken by the MRC was in fact funded with money outside the Rothschild principle.

The health departments themselves have thus pressed MRC into the new arrangement under which MRC must spend an extra £2 million on health services research by 1985. Professor Buller, no fan of the 1973 arrangement, considers this a net gain for health services researchers, who might expect, for example, two or three new MRC units in the area by 1985.

Both Professor Buller and Dr Gowans, however, insist that the definition of health services research must be broad, and that the creation of new units will depend on the availability of good people to head them. The agreement is to be reviewed in five years, when the health departments could

## MRC report in brief

The 1979-80 report makes the following specific points:

**Neutron therapy.** Another £1½ million is needed by the end of this year to buy and set up a new cyclotron for neutron therapy research at Clatterbridge Hospital, Liverpool — which would thus overtake the Hammersmith Hospital, London, in this work. The cyclotron would be outside the MRC budget, and would be funded largely by the Imperial Cancer Research Fund, the Mersey Regional Hospitals Authority, and a Liverpool cancer research fund. But quotations for the equipment expire in December, when inflation would probably put the cyclotron out of reach.

**Tropical medicine.** The Tropical Medicine Research Board of MRC met last Friday for the first time since 1979, having cancelled two meetings for lack of money for research grants since cutbacks in Overseas Development Administration spending in 1979. No new projects could be funded — and overseas cooperation is threatened by the new round of government spending cuts. Recruitment into the field has halted.

**Budgets.** Total expenditure by MRC in 1979-80 was £74 million, including £57 million from the Department of Education and Science and £12.7 million of Rothschild money. The council notes with approval the stability promised in the most recent public expenditure plans, but is apprehensive about the effects of cash limits in inflationary times. Anxious to increase its room for manoeuvre, the council says it has deliberately reduced its commitments to long-term research programmes. During the year, it opened two new research units and closed seven.

**Private practice.** The council has confirmed its longstanding policy that members of the MRC research staff should not be allowed to engage in private medical practice. The review was made necessary by the decision that physicians working for the National Health Service might take on private patients. The MRC council says that private practice would be incompatible with full-time research appointments, promises to secure adequate salaries for those members of its staff concerned and hopes that British universities will follow a similar policy.

Robert Walgate

claw back the money if MRC has not performed according to plan. MRC should undertake "brick upon brick" health services research, says Buller, without the constraint of contracts tied to particular policy objectives. The subject is just at the point of requiring such academic treatment, he believes, and it is best handled under the dual support system. The departments' own £20 million of research money will continue to be spent on pragmatic matters.

Robert Walgate

## CORRESPONDENCE

## Sakharov

SIR—Your journal of 11 September contained a short article by Vera Rich about a conference in the Hague devoted to the "Sakharov affair". On the basis of this article (and I have no grounds for doubting its accuracy, so my grievances are not directed at the author and editors) I was left with the impression that the participants of the conference had received distorted information. This information then reached the pages of your journal. Factual inaccuracies in the description of my situation at the conference and other significant facts and a kind of general demobilizing trend of these inaccuracies aroused perplexity and anxiety, causing me to send this letter to your journal.

I suppose that the participants of the conference and its organizers sincerely wished to help me and others who are suffering from repression, but excessive haste and other errors in its organization have almost cancelled its usefulness.

In my time I have taken part in defending the organizer of the conference, Dr Shtern, but I have never made his acquaintance. I have had no communication with him during the preparation for the conference or at any other time. I am also not acquainted with Dr Lozansky and did not meet him at the Jewish seminar of "refusnik" scientists in Moscow. Shortly before the start of the conference Dr Shtern contacted my representative abroad, Efrem Yankielevich, with a request for him to participate in the work of the conference. Yankielevich declined, expressing some apprehension concerning his unpreparedness, though he submitted some concrete advice about desirable witnesses (which, as far as I know, was not used). Yankielevich also commented on the excessively pretentious (in his, and my, opinion) title of the conference.

The article, however, does not refer to Efrem Yankielevich but to his wife, my adopted daughter Tanya Yankielevich (erroneously called Tamara), who it seems objected to "garish" actions, as if they might interfere with the plans of the Soviet authorities to return me to Moscow. This is not simply an inaccuracy, but something outrageous. A stance that is completely alien to us is ascribed to a person close to me, and thereby, indirectly, to myself also.

I, and persons of a kindred spirit, regard openness as the only weapon in the fight for justice. The plans of the authorities are known to no-one. Our actions and statements must be based on fundamental considerations as we perceive them, without accommodating ourselves to these plans, which are unknown to us, or to anyone's ambitions or other considerations of the political situation. This applies both to my defence, and to the defence of other victims of repression, and to general questions such as disarmament and international security, human rights, environmental protection and nuclear power.

Now to some concrete inaccuracies. In Moscow, publication of preprints of my articles in English was forbidden, and the manuscripts were removed by the KGB from the office of the Institute, evidently to preclude any possibility of acquaintance with my work in the West. The preprints were published at Stanford University, and I am deeply grateful to my colleagues there. I am also very grateful to my colleagues in the USA and in other countries who send me their preprints. The Russian texts of my articles are published in *Zh. éksp. teor.*

*Fiz.* in June, August and September, according to normal schedules. I am confident that the Politbureau has had nothing to do with these publications, and, on the whole, references to the Politbureau without stating the sources of information seem unfounded.

My isolation in Gor'kii is of an entirely different nature than appears from the conference. There is no scientific library opposite my home, to which I might have access. Opposite there is only mud and piles of rubbish. I have no contact with scientists in Gor'kii, not because there are only secret institutes here, but because I am in a state of almost total isolation, deprived of the possibility of meeting anybody at all apart from my wife and two people from Gor'kii, who obtained permission for this from the KGB, and one visit from my university colleague, also by permission of the KGB. Any others are kept away by a militiaman, on duty round the clock, one metre from the door.

I don't even get to know about the majority of visitors, and they have great trouble. After some time I merely learn of people who are close to me. Our friend and doctor, who travelled from Leningrad, was not admitted, nor was our 82-year old aunt from Moscow. They do not even admit my son's fiancée, who has lived with us nearly three years — Liza Alekseeva. The authorities will not allow her out of the country to join the person she loves, she is subjected to persecution, threats of physical and legal reprisals. Fear for her, for her life compels my wife to divide her time between Gor'kii and Moscow. Liza Alekseeva has become a hostage of my public activity, and now her defence is, perhaps, the most realistic form of supporting me.

To describe my situation, I might add that I have no telephone and it is not possible to make a call from a post office; I am deprived of the medical aid of those doctors who used to treat me; my correspondence is carefully inspected by the KGB and only a fraction of correspondence reaches me; in the house where I live there is a personal radio jamming device, which was even in operation before jamming of radio transmissions was resumed in the USSR.

In July my wife found two KGB agents in the flat, who had entered through a window and, without the knowledge of the militiaman on duty, rummaged through my papers, and erased tape recordings. Illegal entry like this, the purposes of which may be even more dangerous, has happened before. I have not received a reply to a single one of my letters or telegrams to officials. Two months ago I sent a letter to the vice president of the Academy of Sciences of the USSR, E. P. Velikhov, and would like to hope for a reply.

The Soviet press, Soviet representatives abroad and some of my Soviet colleagues during foreign missions, in contacts with people in the West who are concerned about my fate, in an attempt to disorganize my defence, assert that I am against détente, have spoken out against SALT, and have even permitted the divulgence of state secrets; they also emphasize the mildness of the measures taken against me. My attitude and open way of life and actions are well known and show how absurd these accusations are.

I have never infringed state secrecy, and any talk of this is slander. I regard thermonuclear war as the main danger threatening mankind, and consider that the problem of preventing it takes priority over other international problems; I am in favour of disarmament and a strategic balance, I support the SALT-II agreement as a necessary stage in disarmament

negotiations. I am against any expansion, against Soviet intervention in Afghanistan, but in favour of aid to refugees and the starving throughout the world. I regard as very important an international agreement on refusal to be the first to use nuclear weapons, concluded on the basis of a strategic balance in the field of conventional weapons. I am convinced of the interrelatedness of international security and defence of human rights, and am in favour of freedom of convictions and exchange of information, freedom to choose one's country of domicile and place of domicile within that country, and freedom of religion. I am deeply anxious about the fate of political prisoners in the USSR, unjust courts, illegal repression. The most important aim for me is the release of prisoners of conscience throughout the world, including the USSR, the countries of Eastern Europe, and China.

I do not make it my task to give special support to the viewpoint of Western governments, or anyone else, but express precisely my own viewpoint on matters causing me anxiety. As for the mildness of the measures taken against me, they are not as severe as the terms of imprisonment lasting many years for my friends and scientists—prisoners of conscience Sergei Kovalev, Yurii Orlov, Toli Shcharanskii (Anatoli Shcharansky), Tanya Velikanova, Viktor Nekipelov, nor as the fate of those awaiting trial — Aleksandr Lavut, Leonard Ternovskii, Tanya Osipova and many others.

But my banishment, without trial in infringement of all constitutional guarantees, the isolation measures applied, interference of the KGB in my life, are completely illegal and inadmissible as an infringement of my personal rights, and as a dangerous precedent of the actions of the authorities, who are casting aside even that pitiful imitation of legality in the persecution of dissidents that they displayed in recent years. Only a court has the right to establish that a law has been infringed and to define the manner of punishment. Any deliberations about culpability and mercy without a trial are inadmissible and against a person's rights.

Therefore I insist on a public trial, and attach fundamental importance to this. It is this that should have been heard at the conference in my defence, and not the greater or lesser mildness of the measures taken against me. Unfortunately, albeit unwittingly, the conference adopted the formulation of the problem that is most advantageous to the Soviet authorities, but even then there were the factual inaccuracies stated above.

I do not know how the fate of others was described (this is not mentioned in the article), but the report concerning the only other person apart from myself mentioned in the article — Dr Gol'fand — is incorrect. He was not dismissed from his work in connection with an application to leave for Israel, but long before he decided to emigrate. Those colleagues of his in the West who are helping him in his struggle for the right to emigrate will, I fear, be misinformed and will cease their efforts after reading such a cheerful paragraph about his reinstatement.

In conclusion I should like to draw attention to the possibility of obtaining accurate information on my situation and attitude directly from my statements and from the reports originating from my wife and from my representative abroad, Efrem Yankielevich.

## NEWS AND VIEWS

## Why is magnetite not a good conductor?

MAGNETITE is a remarkable material, as the first users of lodestones were well aware. When reasonably pure, it looks and feels like a metal. Lumps of magnetite such as can be picked up in some iron mines even sound metallic when struck or thrown to the ground. It is therefore worth recalling that there are some grounds for thinking that magnetite should also conduct electricity as if it were a conventional material. The argument, which of course is false, goes something like this. The crystal structure of magnetite is technically that of the inverse spinel structure. Iron cations turn up on two different kinds of sites within the lattice, conventionally known as A and B sites. The A sites are occupied by  $\text{Fe}^{3+}$  cations and are tetrahedrally related to surrounding oxygen anions. The B sites, on the other hand, have octahedral symmetry and are occupied by equal numbers of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions. This is entirely consistent with the old school textbook notion that magnetite,  $\text{Fe}_3\text{O}_4$ , is a molecular compound of the divalent and trivalent oxides of iron,  $\text{FeO}$  and  $\text{Fe}_2\text{O}_3$ . Considered in isolation, however, the lattice of B sites is potentially a candidate for conduction as if it were a metal. It is possible to think of it as a lattice of  $\text{Fe}^{3+}$  cations with one conduction electron for each pair of cations. How good a conductor of electricity magnetite should be at, say, ordinary temperatures would nevertheless be a matter for detailed calculation and even speculation but one thing would seem to stand out — at some sufficiently low temperature, and certainly near the absolute zero, magnetite should conduct electricity. The fact is that it does not.

If anything, the truth is the opposite. At low temperatures, magnetite has the electrical conductivity of an insulator, but at about 110K there is a first-order transition (recognizable as a specific heat anomaly, for example) and the electrical conductivity of magnetite increases by a factor of about 100 to  $100\ \Omega^{-1}\text{cm}^{-1}$ . With further increase of temperature, the conductivity increases by a further order of magnitude until, as with all conductors, the disruptive effects of lattice vibrations eventually take over and the conductivity decreases with increasing temperature. The conductivity of magnetite above 110K is thus more or less what would be expected. The puzzle is to know why the material does not conduct at lower temperatures. The explanation is by no means novel, although it retains something of the flavour of a surprise. It appears that at low temperatures magnetite is not a conductor because, below the transition temperature, the electrons from the cations at B sites arrange themselves in such a way that there is some form of long-range ordering of the  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions. So much was guessed at in the 1940s by E. J. W. Verwey, after whom are now named transitions from states in which ionic charges are ordered to states in which they are not. It is salutary, therefore, to be reminded that people are still unsure what happens to magnetite below 110K. So much at least is clear from the issue of the *Philosophical Magazine* (Series B, Volume 42) for September 1980.

Magnetite is by no means the only material now known to exhibit transitions of this kind. The oxide of titanium with the composition  $\text{Ti}_4\text{O}_7$  is another. The low-temperature state in which electrical conduction is inhibited consists of an ordered arrangement of  $\text{Ti}^{3+}$  and  $\text{Ti}^{4+}$  cations. But there are also materials typified by the samarium sulphide  $\text{Sm}_3\text{S}_4$  in which cations of different charge (in this case  $\text{Sm}^{2+}$  and  $\text{Sm}^{3+}$ ) sit on the same lattice and appear not to form a highly ordered (and thus a markedly non-conducting) state at low temperatures. Why should there be these differences? And why, in any case, is it turning out to be so difficult to come to grips with properties of

what might at first sight seem to be among the simplest of phase transitions? The special issue of *Philosophical Magazine* consisting of papers stimulated by a symposium on the Verwey transition a year ago at the Cavendish Laboratory, and obviously fostered by Sir Nevill Mott, for long the editor of the journal and who contributes an introductory paper, is a splendid way of finding out.

The first surprise is that, until very recently, the actual arrangement of the cations in magnetite at low temperatures was in doubt. That this should have been the case is no surprise if the ordered structure now described by S. Iida (*Phil. Mag. B* 42, 239; 1980) is anything like correct. Especially in the past few years, data bearing on the structure of magnetite at low temperatures have been derived from a variety of sources — Mossbauer spectroscopy, nuclear magnetic resonance measurements and neutron diffraction. The underlying difficulty is that any state in which there is long-range order of cations of different electrical charges on the B sites of the lattice is bound to entail substantial distortion of the shape of the lattice. (Some lattice distances are indeed changed by more than two per cent.) Iida's solution to what is plainly a problem of great complexity involves the description of a superlattice in which eight unit cells in the inverse spinel structure become a single unit cell in a lattice with a larger repeating unit. In the ordered state, below the first-order transition at 110K,  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  cations turn up as pairs or as groups of three similar cations in a row. Although the outcome of the tortuous chain of inference leading to this conclusion is outwardly simple, it is easy enough to see why it could not have been predicted, and why even now its calculation would be a formidable undertaking.

The complications are indeed even more serious than might be thought. Magnetite is not a simple conductor (above the Verwey transition) or a simple insulator (below). The interaction between the relatively large magnetic moments of the cations on the A and B sites makes magnetite a ferromagnetic material below the relatively high Curie temperature of 850K or thereabouts. (The large influence of small quantities of impurities makes the temperature uncertain.) The result is still greater strain of the lattice structure. But magnetite is also a ferroelectric at low temperatures, making for even more lattice distortion. Against this background, the recognition in recent years of further low-temperature transitions (recognizable as specific heat anomalies) is to be expected. The experimental difficulty is that the transition temperatures are sensitive not merely to the stoichiometric purity of the magnetite but to its physical condition. Iida's paper points to an explanation of the transition at 12 K, but there remains room for further argument.

The properties of  $\text{Ti}_4\text{O}_7$  are similarly complex, although C. Schlenker and M. Marezio from the CNRS in Grenoble have a somewhat simpler tale to tell (*Phil. Mag. B* 42, 453; 1980). Two distinct first-order transitions are recognized and, at the lowest temperatures, pairs of titanium cations of different charge are frozen into the lattice. Between the two transition temperatures, pairs can migrate by a process described as 'hopping' and then, at high temperatures, long-range order disappears and the conduction becomes possible. The explicit calculations of what may be happening purport to be little more than crude approximations. Plainly, the experimentalists will make the running for some time to come. Indeed, the study of this curious and still somewhat unexpected transition is likely to serve chiefly as a pointer to fresh problems in lattice structure. □

# Molecular genetics of the mouse

from Grahame Bulfield

WORKERS from two rather different areas came together at a recent conference\* in an attempt to relate structure to function in the regulation of mammalian gene expression. One group of workers has been studying the large number of structural and regulatory gene loci controlling enzyme levels that have been discovered in the mouse. A second group, exploiting recent advances in molecular biology, has been looking at the arrangement and sequence of some mammalian structural genes.

The system most completely characterized by genetic analysis in the mouse is that of  $\beta$ -glucuronidase (K. Paigen, Buffalo; see also *A. Rev. Genet.* **13**, 417; 1980) and by molecular techniques is the globin system (H. Dahl, National Institute of Medical Research, London). However, the only gene family where both approaches have already converged is the amylase one. Genetic analysis shows that the genes for pancreatic and salivary amylase isoenzymes are tightly linked. The different pancreatic isoenzymes are coded for by up to 20 tandemly repeated structural genes (T. Nielsen, Aarhus) but the sole salivary isoenzyme is the product of a single locus (J.P. Hjorth, Aarhus). These workers have identified over 20 different haplotypes of the complex in wild-caught mice and backcrossed them into the C3H inbred strain. Some of the genetically distinct pancreatic isoenzymes have been characterized by peptide analysis and partial amino acid sequencing (M. Meisler, Ann. Arbor). The A/J inbred strain has one salivary and one pancreatic isoenzyme and a single mRNA species is present in each tissue. The active salivary and pancreatic genes are respectively about 28 and 13 kilobases long and contain at least ten exons. Overall there is a family of about eight amylase-like genes, including one salivary gene, but six of the genes are not expressed in the A/J strain (R. Young, Lausanne) demonstrating a remarkable fit with the genetic evidence. The rat amylase gene has also been cloned as part of an analysis of the structure of the pancreas-specific genes and 12 amylase-like genes have been found (W. Rutter, University of California, San Francisco). The complimentary approaches of the geneticists (in providing a large number of congenic haplotypes) and of the molecular biologists (in providing methods for analysing gene structure) should produce a much better understanding of the regulation of expression of the amylase system.

The workshop provided many reports of new variation available to geneticists, the

characterization of some of the systems and their use in analysing both the regulation of gene activity and of development. Expression of  $\beta$ -glucuronidase is affected by several regulatory loci which map at or near the structural gene and control systemic levels of the enzyme, androgen inducibility and developmental profile (K. Paigen; K. Pfister, Zürich). The different haplotypes of this gene complex should provide valuable analytical material once the gene has been cloned.

Genetic variation in regulatory or tissue-specific mechanisms was reported for many enzyme systems including: alcohol-metabolizing enzymes (R. Holmes, Brisbane), H-2 and related systems (M. Boubelik, Prague; K. Fisher Lindahl, Basel), glycerophosphate dehydrogenase (L. Kozak, Bar Harbor), histidine decarboxylase (S.A.M. Martin, Leicester University), metallothioneins (D.M. Hunt, Queen Mary's College, London), neuraminidase (J. Peters, Harwell) and pyruvate kinase (K.J. Moore, Leicester University). Novel methods of investigating genetic regulation were introduced for teratocarcinomas (W.F. Dove, Madison), by the use of spontaneously occurring trisomics (A. Gropp, Lübeck; R. Fündele, München) and by the flow sorting of mammalian chromatin (L. Bolund, Aarhus). Many of the variants in the enzyme systems listed above have unusual features suggesting that the complexities of genetic regulation will be various and may be difficult to unravel. Further extensive genetic variation, so far little used, was shown to be available in different species (interfertile with laboratory mice) and sub-species of feral mice throughout Eurasia (L. Thaler,

Montpelier; E. Capanna and A. Gropp, Rome/Lübeck; K. Moriwaki, Mishima).

The use of biochemical variants to analyse the nature of one developmental problem — X-chromosome inactivation — was discussed in depth. An electrophoretic variant of G6PDH found in *Mus caroli* has been used to show that, in the germ cells of heterozygous fetuses, one X chromosome is active at the 10th day *post coitum*, whereas both are active between days 11 and 14 *post coitum* during the leptotene to pachytene stage of meiosis (V. Chapman, Buffalo). A 'Catherine-wheel' model has been proposed to incorporate the X-chromosome activation-inactivation cycle in the germ cells with the progressive X-inactivation of extraembryonic and embryonic tissues during fetal development (as demonstrated by gene dosage of X-linked enzymes and X-linked electrophoretic alloenzymes (M. Monk, M. Harper and A. McMahon, University College London). That X-inactivation may itself be under genetic control was shown by three alleles of the *Xce* locus which modify the extent of inactivation on the X chromosome they inhabit (B. Cattaneach, Harwell).

Most of the discussions that took place during the conference were concerned with the validity of the genetical and molecular approaches and how they might compliment one other. Two important points were made: first, the need to concentrate on a few systems and analyse them in detail and second, the need to overcome the geneticists' inability to obtain recombinants between structural and regulatory loci within a tightly linked gene complex. Such recombinants will be essential to relate different DNA sequences to changes in phenotype. □

Grahame Bulfield is a Lecturer in Genetics at the University of Leicester Medical School.

## Are QSO absorption lines extrinsic?

from Derek Wills

THE observation of quasi-stellar objects (QSOs) in the ultraviolet (UV), made possible by rocket and satellite developments in the past few years, promises to help decide between alternative explanations of some properties of these still puzzling objects. One of the latest developments is that improved measurements of 3C273 in the UV lend support to the hypothesis that the absorption lines in the spectra of this and other QSOs are due to intervening galaxies (or other material) and that they are not intrinsic to the QSOs themselves.

Derek Wills is associate professor of astronomy at the University of Texas, Austin.

The first QSO whose redshift was determined is the radio source 3C273, which was observed spectroscopically by M. Schmidt (*Nature* **197**, 1040; 1963). Although more than 1,500 QSO redshifts are now known, 3C273 is still the brightest (magnitude 13) and has almost the smallest redshift (0.16). Observations of 3C273 in the UV region are of particular interest because, at this relatively small redshift, it is possible to examine a spectral region that is seen from the ground only in QSOs at much larger redshifts. The result is a direct comparison of physical conditions in objects at quite different cosmological distances and, thus, at different cosmological epochs. Study of the UV

\*Workshop on the Molecular Genetics of the Mouse II held at Sandbjerg Slot, Sønderborg, Denmark, on 11-16 August, organised by J. Peter Hjorth of the Institute of Ecology and Genetics, University of Aarhus and supported by the Danish Natural Science Research Council and Gl. Bomholtgaard Ltd. The abstracts will be published in *Hereditas*.

absorption-line spectrum also makes it possible to probe the medium between 3C273 and the Earth.

The first UV observations of 3C273 were made from a rocket (A. Davidsen *et al.* *Nature* **269**, 203; 1977) and were soon followed by broad-band UV measurements from the ANS satellite (C.-C. Wu *Astrophys. J. Lett.* **217**, L117; 1977). Not surprisingly, 3C273 was one of the small number of extragalactic objects observed during the commissioning phase of the International Ultraviolet Explorer (IUE) satellite by a team of twenty-six astronomers (A. Boksenberg *et al.* *Nature* **275**, 404; 1978), and two separate groups then obtained more detailed spectra of the QSO. One team published their results last year (A. Boggess *et al.* *Astrophys. J. Lett.* **230**, L131; 1979) and the latest contribution, by M.-H. Ulrich *et al.* (*Mon. Not. R. astr. Soc.* **192**, 561; 1980), is a collaborative effort by twenty astronomers at twelve institutions in five European countries. These spectra represent a total of about 16 hours of observing time with the 45-cm diameter telescope on board IUE, and their quality is comparable with those of spectra obtained by ground-based telescopes observing much fainter QSOs at larger redshifts.

It was clear from the first rocket spectra of 3C273 that its emission-line spectrum is indistinguishable from those of typical QSOs at large redshifts, and the details now reported reinforce this conclusion. The similarity is perhaps not as surprising as the fact that the emission-line spectra of QSOs at even the earliest cosmological epochs can be satisfactorily reproduced by simple models involving photo-ionization of a gas with chemical element abundances similar to those in the Sun. The underlying continuum of 3C273 can be represented fairly well by a power law over a large frequency range, except for a considerable excess of radiation in the UV-optical region. It was suggested by G.A. Shields (*Nature* **272**, 706; 1978) that this excess is attributable to thermal radiation from the vicinity of the black hole that is supposed to supply the enormous energy emitted by QSOs, and the observations of Ulrich *et al.* lend support to this interpretation of the UV-optical excess, in part by excluding some other suggested mechanisms.

The absorption-line spectrum of 3C273 is of particular interest. Virtually all large-redshift QSOs contain one or more sets of narrow absorption lines, usually at smaller redshifts than the corresponding emission lines. The strongest absorption lines are due to Lyman- $\alpha$  of hydrogen and other transitions in the UV, so that they are detectable from the ground only when the redshifts are large.

There is long-standing argument about the origin of these absorption lines. One interpretation is that they are caused by clouds of material ejected at high speeds (up to 0.1–0.5 of the speed of light), perhaps by the radiation pressure of the

QSO; another is that they arise in normal galaxies or intergalactic clouds that happen to intersect the very long path between us and the QSO. The two explanations are not mutually exclusive, although the minority of astronomers who still doubt the cosmological interpretation of QSO redshifts (see the recent review by G.R. Burbidge in *Nature* **282**, 451; 1979) cannot accept the second.

An obvious prediction from the ejection hypothesis is that absorption systems should be seen in nearby QSOs just as frequently as in the distant ones; even if, as in the early rocket observations, the wavelength resolution is not quite sufficient to detect individual, narrow absorption lines, the blending of lines below the wavelength of the Lyman- $\alpha$  emission should produce a noticeable drop in the continuum level in that part of the observed spectrum. On the other hand, if the 'intervening galaxy' hypothesis is valid, a relatively nearby object such as 3C273 would be unlikely to show displaced absorption lines or a drop in the continuum level below the Lyman- $\alpha$ .

No such change in the continuum level has been unambiguously seen in any of the UV spectra of 3C273, and the improved data from Ulrich *et al.* still show no evidence for individual absorption lines like those seen in high-redshift QSOs. Adherents of the ejection hypothesis will probably reply that observations of more than one low-redshift QSO are needed before their model can be ruled out, and that large ejection velocities (greater than about one-fifth that of light) would place the strong Lyman- $\alpha$  absorption below the IUE low-wavelength limit.

The latest data on the absorption lines in 3C273 also improve on the earlier evidence for absorption lines at zero redshift, arising in our galaxy. In particular, Ulrich *et al.* confirm the earlier IUE evidence (Savage and de Boer *Astrophys. J. Lett.* **230**, L77;

1979) for absorption due to CIV at 1,549 Å. This line indicates the presence of a highly ionized region at a temperature of  $\approx 10^5$  K, and confirms the prediction (L. Spitzer *Astrophys. J.* **124**, 20; 1956) that our galaxy possesses a hot, gaseous corona, perhaps as a result of accretion of hot, intergalactic gas (D. Sciama *Nature* **240**, 456; 1972) or supernova explosions in the disk.

The presence of the CIV line in some of the absorption systems seen in high-redshift QSOs was formerly used as an argument against the 'intervening galaxy' model, on the grounds that there was no convincing evidence for such high temperatures and metal abundances in the haloes of normal galaxies. The detection of this spectral line in our own galaxy at roughly the intensity seen in the absorption spectra of high-redshift QSOs clearly removes this objection. Thus the presence of absorption lines at zero redshift and their absence at other redshifts must both be counted in favour of the idea that intervening galaxies similar to our own are responsible for many of the QSO absorption-line systems.

Undoubtedly, 3C273 will be among the first objects observed when the Large Space Telescope is launched in a few years. That eagerly awaited development will greatly increase the number of low-redshift QSOs whose UV spectra can be examined, perhaps leading to final agreement on the origin of QSO absorption lines and to a more detailed comparison of conditions in objects believed to have been formed at quite different cosmological epochs. In the meantime, the latest observations confirm that we can now use UV observations of QSOs as probes of the hot, outer regions of our galaxy — for even if there is still some lack of unanimity about QSO distances, there is at least agreement that they are outside our own galaxy. □

## Biosynthesis and processing of cellular and viral polyproteins

from Edward Herbert

THAT active forms of polypeptides can be generated from inactive forms by proteolytic cleavages is an idea dating back to the discovery of precursor forms of gastrointestinal proteases (zymogens) in the early thirties. This type of activation is now known to occur with polypeptide hormones, proteases, blood coagulation factors and viral proteins. The activation process can be either an intracellular or extracellular event and is usually accomplished by trypsin-like enzymes.

Edward Herbert is Professor of Chemistry at the University of Oregon.

The discovery of viral and cellular proteins that serve as precursors to more than one biologically active entity has added a new level of complexity to the subject of protein processing.

At a recent conference\*, scientists working on cellular and viral polyproteins were brought together to discuss similarities and differences in processing of these two classes of proteins.

Among the cellular proteins, pro-opiomelanocortin and proneurophysins

\*Held in Hamburg, FRG in May 1980.

have attracted the most interest. Pro-opiomelanocortin, which contains 260 amino acids, is the precursor to adrenocorticotropin (ACTH),  $\alpha$ - and  $\beta$ -melanocyte-stimulating hormones (MSHs),  $\beta$ -lipotropin ( $\beta$ -LPH) and  $\beta$ -endorphin [ $\beta$  (61–91)LPH]. The amino acid sequence of the precursor was worked out in 1979 by Nakanishi *et al.* (*Nature* **278**, 423, 1979) using recombinant DNA technology. This revealed that each biologically active domain in the precursor is preceded by a tryptic cleavage site (Lys-Lys or Lys-Arg). At the Hamburg meeting, A.C.Y. Chang (Stanford University) presented a partial sequence of the human pro-opiomelanocortin gene. One intron was found at a position 93 amino acids from the amino terminus of the protein but no other interruptions of the coding sequence were detected showing that genetic information for ACTH and  $\beta$ -LPH is contiguous. M. Chrétien (Montreal) presented the amino acid sequence of a 103-amino acid N-terminal fragment of the precursor isolated from the human pituitary. Sequencing work revealed two N-terminal amino acids (Trp and Arg) suggesting that there may be two pro-opiomelanocortin genes in humans.

Pro-opiomelanocortin is present in both anterior and intermediate lobes of mouse and rat pituitary (E. Herbert, University of Oregon). However, the precursor is processed to different end products in the two lobes. The major end products in the anterior lobe are glycosylated and unglycosylated forms of ACTH,  $\beta$ -LPH and N-terminal fragments of the precursor. In the intermediate lobe ACTH is processed further to  $\alpha$ -MSH and  $\beta$ -LPH is processed to  $\beta$ -endorphin. The initial core glycosylation of the precursor and the first proteolytic cleavage appear to be the same in the two lobes, suggesting that processing differences in the two tissues arise at later stages. In the intermediate lobe of rat pituitary,  $\beta$ -endorphin [ $\beta$  (61–91)LPH] is rapidly converted to an N-acetyl derivative and a derivative missing four C-terminal amino acids (Zakarian, National Institute of Medical Research, London). These derivatives, which account for most of the endorphin in the intermediate lobe, have no opioid activity. In contrast to this situation, the major form of endorphin in the hypothalamus is  $\beta$ -endorphin.

Processing of pro-opiomelanocortin occurs quite early in the secretory pathway as subcellular fractions from rat pituitary enriched in endoplasmic reticulum and Golgi vesicles have a precursor/product ratio of 10. This ratio reaches a value greater than 100 in subcellular fractions enriched in secretory vesicles (Glembotski, University of Colorado). Loh (National Institutes of Health) showed that processing of pro-opiomelanocortin in the intermediate lobe of toad pituitary is similar to that in rat pituitary, and that inhibition of

glycosylation by tunicamycin leads to enhanced intracellular degradation of pro-opiomelanocortin to atypical peptides.

Considerable progress has been made in the past year in the study of the synthesis of neurophysins I and II. Three groups reported the synthesis of pre-pro-forms of neurophysins I and II in cell-free protein-synthesizing systems operating under the direction of hypothalamic mRNA (Chaiken, National Institutes of Health; Richeter, University of Hamburg; McKelvy, University of Pittsburgh). Pre-pro-neurophysin I has a molecular weight of 17,000–19,000 and contains an antigenic determinant for oxytocin. Pre-pro-neurophysin II has a molecular weight of 23,000–25,000 and contains an antigenic determinant for vasopressin (Richter). Peptide mapping studies confirm the presence of the neurophysin sequences in pre-pro-neurophysins I and II but sequences of vasopressin and oxytocin could not be detected (Chaiken). The possibility that still higher-molecular-weight forms of neurophysins exist was raised by P. Cohen (University of Paris) who fractionated hypothalamic proteins by gel filtration in denaturing solvents. A protein moiety of molecular weight greater than 50,000 was reported to contain antigenic determinants of neurophysins I and II and oxytocin and vasopressin.

Do these findings about polyprotein precursors of hormones and other biologically active entities have any relevance to what has been found for viral polyproteins? Host cell proteases are most likely involved in very early steps (initial translation of a polyprotein) or in very late steps (transport through membranes or at maturation) of viral replication. In addition, proteolytic enzymes are synthesized by many viruses that are responsible for very specific steps in protein processing. Finally, interesting modifications of viral proteins take place as prerequisite for or as the result of function.

For example, the initial cleavage of the polyprotein of picornaviruses (molecular weight 220,000) is likely to occur by a host cell protease. Such function could reside in the 80S ribosome (Korant, University of Wilmington). One of the initial cleavage products of the polyprotein of encephalomyocarditis virus (a picornavirus), on the other hand, is capable of autocatalytic cleavage yielding a virus-specific protease, p24, which in turn processes other viral proteins (Rueckert, University of Cleveland). In contrast, the precursor protein Pr76<sup>gag</sup> of avian retroviruses is incapable of autocatalytic cleavage, although its C-terminal portion (p15) is a virus-specific protease. p15 must be generated first by a host function before it can proceed to process the rest of the viral precursor protein (Eisenmann, University of Washington; Dittmar, University of Berlin). Both p24 of encephalomyocarditis virus and p15 of retrovirus have a narrow

range of specificity but a definition of their action must await further studies on the structure of viral proteins.

Late reactions in viral maturation taking place as the virus buds from the cell in the completed viral particle were also discussed. Evidence was presented for the involvement of several proteases with unique specificities in cleavage of murine leukaemia virus proteins during viral morphogenesis (Luftig, University of Ohio). One activity exhibited characteristics of serine proteases, another hydrolysed two X-Pro bonds (with X being either tyrosine or phenylalanine). The haemagglutinin of influenza virus also has to be hydrolysed at a critical site to expose a new amino-terminal region which is crucial for infectivity (H.-D. Klenk, Giessen). This cleavage requires a trypsin-like enzyme which must be supplied by the host. Other proteases may cleave adjacent peptide bonds but this does not yield infectious viral particles. A similar example has been described in the maturation of Semliki Forest virus — in cells infected with this virus, a 26S mRNA is produced which codes for a polyprotein cleaved into capsid protein and two transmembrane proteins. The nucleotide sequence of the 26S mRNA has recently been completed (H. Garoff, Heidelberg) and it was found to contain an uninterrupted reading frame which can code for more than 1,200 amino acids. In conjunction with data on the termini of mature virus proteins, the cleavage sites, membrane-spanning segments and putative signal sequences can be discerned. Interestingly, the last cleavage of this polyprotein, the extracellular processing of the transmembrane protein p62 to yield proteins E2 and E3, again involves a trypsin-like specificity.

Viral glycoproteins undergo cleavage by host cellular signal peptidase while being transported to the cell surface. The value of viral proteins as probes to study modification and transport of polypeptides was documented by Lodish (University of Cambridge), who also discussed the interesting phenomenon of fatty acid acylation of certain cellular and viral glycoproteins. Another novel modification of polypeptides is the polyadenylation diphosphate ribosylation of some reovirus capsid proteins (Carter, State University of New York), a phenomenon that may play a role in regulating events in reovirus morphogenesis. Finally, all newly synthesized viral RNA of poliovirus is covalently linked to a small protein, VPg, at the 5' end via a  $O^4$ -(5'-uridylyl)-tyrosine bond (Wimmer, State University of New York). VPg maps in the precursor (NCVP1b) for the viral RNA polymerase as well as viral protease (Rueckert; Wimmer). Since no free VPg can be detected in the infected cell, initiation of RNA synthesis may be linked to a step of proteolytic cleavage of the precursor for the viral RNA polymerase, a situation unique among animal RNA viruses. ■

# Lessons from a peptidergic neurone

from B. T. Pickering

SECRETED polypeptides are known to begin their lives as parts of larger precursors but for many biosynthetic pathways the question persists of 'how large is larger'. This question has recently been asked for the precursors of vasopressin by Paul Cohen and his associates in Paris (*Proc. natn. Acad. Sci. U.S.A.* 77, 2587; 1980). They have found evidence, primarily based on Sephadex chromatography in the presence and absence of urea, of a large ( $\approx 140,000K$ ) precursor molecule in beef posterior pituitaries which showed immunoreactivity with both antivasopressin and antineurophysin sera.

The posterior pituitary hormones were the first recognized members of the neuropeptides, a group which has been growing in both size and importance. Although the hormones oxytocin and vasopressin are released from the posterior pituitary, the gland consists essentially of a collection of the ends of nerve fibres whose neuronal cell bodies are located in the supraoptic and paraventricular nuclei of the hypothalamus. Protein synthesis occurs only in the cell body but the synthetic product is packaged into granules and transported along the nerve fibres for storage in, and release from, the posterior pituitary gland. Along with the non-peptide hormones, the gland contains a family of polypeptides with molecular weights around 10,000 — the neurophysins. These molecules form strong ionic complexes with the hormones with a *pH* optimum of 5.5, close to that inside the secretory granule. It is not surprising, therefore, that neurophysins have been regarded as carrier proteins necessary to keep the hormones inside the granules during their intra-axonal journey.

The hypothesis that vasopressin and its neurophysin share a common precursor was first put forward by Howard Sachs in the mid-sixties. Sachs and Takabatake

(*Endocrinology* 75, 943; 1964) presented the first real evidence for post-translational processing of a polypeptide hormone precursor and the group went on to include neurophysin in the precursor, summarizing their views at the same Laurentian conference that received Steiner's evidence for the existence of proinsulin (*Recent Prog. Horm. Res.* 25; 1969). The hypothesis became much more plausible when it was realised that almost all species elaborate at least two neurophysins — one which is biosynthetically related to vasopressin and another related to oxytocin. Other minor neurophysins seem to be metabolic products of these two (see *Ann. N. Y. Acad. Sci.* 248; 1975).

Undoubtedly the major breakthrough in this field, which provided some hard data to back up the circumstantial evidence, came from Hal Gainer and his group at the US National Institutes of Health (*J. Cell Biol.* 73, 366; 1977; *Science* 207, 373; 1980). In brief, the Gainer group has used pulse-chase studies to show that the two major neurophysins of the rat are formed from two precursors ( $\approx 20,000K$ ) and that processing continues within the secretory granule while it is travelling along the axon. Although the NIH group has not been able to demonstrate conclusively that the precursors do contain hormone as well as neurophysin sequences within their molecules, they have shown that the putative vasopressin precursor is absent from animals unable to make vasopressin (Brattleboro rats). Also, after limited tryptic digestion, the precursor produces molecules with characteristics similar to vasopressin as well as to neurophysin.

The recent paper of Cohen *et al.* (*op. cit.*) reports evidence for a similar ( $\approx 25,000K$ ) precursor in beef pituitaries and this did have immunological determinants for both neurophysin and vasopressin, as did the larger ( $\approx 140,000K$ ) component.

Moreover, protease activity generated molecules with the characteristics of the fully processed secretory products. Similar 20,000–25,000K neurophysin precursors have been synthesized in cell-free systems using mRNA extracted from the supraoptic nuclei of cattle by Guidice and Chaiken (*Proc. natn. Acad. Sci. U.S.A.* 76, 3800; 1979) and of mice by McKelvy and colleagues (*Biochem. biophys. Res. Commun.* 89, 943; 1979). The neurophysin (10,000) and hormone (1,000) sequences would account for about 11,000 of the precursor molecular weight, leaving some 10,000 to be accounted for, and Gainer's group has evidence that in the putative vasopressin precursor this is represented by a 10,000K glycopeptide.

Thus the 20,000–25,000K precursor can be readily accounted for in terms of processed products and has an extractable mRNA to direct its synthesis. What constitutes the residual 110,000 in the larger molecule? Does it form part of the biosynthetic pathway? Certainly there seem to be comparable amounts of 140,000 and 25,000K forms remaining in the granules when they reach the posterior pituitary gland where processing is all but complete (96%). If the 140,000K form is an early stage of the usual pathway, the products of the residual 110,000 should be present in the secretory granule in amounts equimolar with neurophysins and hormones. If not, it must follow that the 140,000K form is a polymer of the 25,000K precursor, perhaps coming from the translation of a polycistronic message; such a possibility is allowed by the Paris workers. The solution to this problem, along with the exclusion of aggregation arising from disulphide interchanges, must await a re-examination of pulse-chase studies in the hypothalamus where precursor/product ratios are more favourable than in the posterior pituitary.

Quite apart from the size of the primary translation product, in my view (*Essays in Biochemistry* 14, 45; 1978) the great attraction of the hypothalamo-neurohypophyseal system is that it provides a good model system for studying polypeptide secretion. Its constituent neurones show all the properties of secretory cells but there is a division of labour (see Fig. 1) such that synthesis and packaging take place in the perikaryon, transport of granules occurs along the axon, and storage and release of the product is restricted to the nerve terminal. This permits the constituent phases of secretion to be studied in some degree of isolation one from another, leading, for example, to the evidence that processing continues while the granule is in

Fig. 1 The division of labour in a peptide-secreting neurone. (After an idea by N. McC. Mortensen.)

B. T. Pickering is a Professor of Anatomy at Bristol University, UK.

transit. The peptidergic neurone as a model system was the dominating theme of the recent 8th International Symposium on Neurosecretion\*. Also at this meeting, H.-D. Dellman (Iowa) showed that, in the developing neurone, secretory material appears within the cisternae of the endoplasmic reticulum before the appearance of Golgi complexes or secretory granules. It is tempting to relate this observation to the almost simultaneous report of A. G. Robinson (Pittsburgh), at another meeting†, that while immunoreactive neurophysin appeared in the brains of fetal

\*Held at Friday Harbor, Washington on 4–10 September 1980

rats on day 13 of gestation, peaked on day 14 and fell slowly towards term, the hormones were undetectable on day 13 but their content in the brain increased towards term. If, as Robinson suggests, these results reflect a high relative concentration of precursor forms in the third fetal week, then, taken together with Dellman's findings, they suggest that the developing hypothalamo-neurohypophysial system presents a tool for the study of the role of the Golgi complex in precursor processing. □

## The search for the Zvolen fireball

from David W. Hughes

FIVE all-sky camera stations of the European Fireball Network recorded a bright fireball which penetrated low into the atmosphere on 27 May 1979 at 20h 39min. The fireball terminated close to Zvolen in central Slovakia and may have produced several meteorites.

Geometric, dynamic, photometric and orbital data have been calculated by Z. Cepelach, J. Boček and M. Ježková of the Astronomical Institute of the Czechoslovak Academy of Sciences, Ondřejov, V. Porubčan of the Astronomical Institute of the Slovak Academy of Sciences, Bratislava and G. Polnitzky of the University Observatory, Vienna. Their results have been published in a recent edition of the *Bulletin of the Astronomical Institutes of Czechoslovakia*

31, 176; 1980.

The photometric and positional data on all the available photographic records were measured using a Zeiss Ascocord device. Computational analysis gave the light curve shown in Fig. 1. It is interesting to note that the magnitude remained reasonably constant during a considerable portion of the trajectory. The luminous power is approximately proportional to the kinetic energy lost per unit time by the incident body and it can be seen that mass loss dominates the constant luminosity phase. The maximum deceleration occurs well inside the luminous trajectory and this is typical for meteorite-dropping fireballs. The end height, coupled with the initial mass, velocity and trajectory, indicates that the meteorite was an ordinary

chondrite (a 'strong' stone). The low initial velocity is responsible for the maximum luminosity occurring between heights of 60 and 30 km. Two of the photographs showed the separation of three fragments from the main trail. Fragmentation occurred at heights of 28, 33 and 40 km.

The computational analysis also gave the orbit of the incident meteorite. This had a perihelion distance of 0.89 AU (just inside the Earth's orbit), an aphelion distance of 2.84 AU (right in the asteroid belt) and an inclination to the ecliptic of only 2.3°.

The mass of the final falling meteorite and fragments was estimated to be a kilogram or so. The statistics of meteoritic events from fireball camera networks in the American and Canadian Prairies, demonstrate that one observable meteorite fall per year should occur within a network area of about  $1.4 \times 10^6 \text{ km}^2$ . As the cameras can only register fireballs efficiently when the sky is completely dark, the influx rate of meteorites will be about three times higher than this figure. This is equivalent to about 1,100 meteorite falls per year over the whole surface of the Earth and about 300 over the land masses. In the regions where the networks are active it has been found that the searches that follow the observed falls only have, on average, a 10 per cent chance of recovering the meteorite. Under these assumptions, the Slovakian part of the European network should observe a meteorite fall every 30 years and recover one every 300 years.

The search area for the Zvolen meteorite was estimated to be about  $10 \text{ km}^2$ . This is larger than usual. The photographic station which predicts the fall site most accurately is the one closest to the terminal point of the luminous trail. The camera at Močiar was only 15 km from the predicted position but the gremlins that haunt all scientific endeavour were at work. The Močiar camera was opened on that evening two minutes after the apparition of the fireball. The central part of the search area lies in the eastern part of the town of Zvolen, a region containing many urban dwellings, two large factories, a railway depot with piles of coal and a small river that is swampy in parts. The other regions of the predicted fall area are hilly and covered with woods, fields and meadows. The possibilities of finding a strange, 1-kg rock, about 10-cm across, do not seem too great.

Great publicity was given to the event in the hope of obtaining eye-witness reports of the fireball flight near the impact point. It was surprising that only seven reports were forthcoming in a region of such dense population and only two reports helped to reconstruct the whole path of the flight.

Well over a year has passed, including an early spring when vegetation is much thinner than usual. Nothing has yet been found. □

David W. Hughes is in the Department of Physics, University of Sheffield.

Fig. 1 The light curve of the Zvolen Fireball over the brightest part of its trajectory. The left ordinate gives the absolute photometric magnitude, which is the magnitude the fireball would have if it was at a standard position 100 km from the observer at the zenith. The right-hand ordinate gives the brightness, standardized so that a brightness of 1 arbitrary unit is equivalent to an absolute magnitude of -4. The main abscissa is time, measured in seconds. Secondary abscissae show the decrease in the height of the causative meteorite and also its mass loss and deceleration. At  $t = 0$ , the meteorite had a calculated mass of 223 kg and a velocity of  $16.12 \text{ km s}^{-1}$ .

## REVIEW ARTICLE

## The diffuse UV background

Francesco Paresce &amp; Peter Jakobsen\*

Space Sciences Laboratory, University of California, Berkeley, California 94720

*The diffuse radiation field in the UV (900–3,000 Å) affects the structure of galactic molecular clouds and conveys important information concerning the physical characteristics and spatial distribution of gas and dust in the Universe. Continuum emission in this range is probably dominated by interstellar dust scattering in our Galaxy. For view directions and angular resolutions allowing observations in the rifts between galactic dust clouds, the background due to the integrated light of spiral galaxies may be detected, providing important information on their structure and evolution. The redshifted emission from an intergalactic medium may be observable in the regions between nearby bright galaxies. Present observations provide weak constraints on the radiation field required to ionize the intergalactic medium at the level required by the Gunn–Peterson test.*

THE recent enhanced capabilities of UV instrumentation and observing platforms, a better understanding of basic emission processes coupled with rapid progress in associated fields (especially dust grain characteristics and distribution and galactic luminosity functions) have contributed to a rapid growth of diffuse UV astronomy. UV spectra of galaxies from the OAO, IUE and ANS satellites have enabled their contribution to a diffuse background in the UV to be assessed. New optical observations of hot objects and of high latitude reflection nebulae have become useful for probing the origin of the observed UV radiation field and assessing the likelihood of reaching extragalactic sources.

These factors make the present situation more complex than that envisaged by Davidsen *et al.*<sup>1</sup>, but there are still conflicting observations indicative of the fundamental difficulty of observation. We attempt here, using these latest findings, to determine as accurately as possible the characteristics of the most likely sources of the diffuse UV background. We have placed special emphasis on assessing the probability that information of cosmological significance can be gleaned from this work. Galactic dust and external galaxies are likely to have an important role. These sources must be well understood before the intergalactic medium contribution, if any, can be properly quantified especially if it is emitting by recombination radiation rather than collisional excitation as has been assumed in the past.

### Local sources

The most serious difficulty in analysing diffuse cosmic background data from UV instruments is to account for the large number of sources that may contaminate the observations. The inherent instrument background is not as easily removable for diffuse emission spectrophotometry as it is for point sources. Shutters that can exclude the outside world periodically are the only reliable method, but complex moving parts in spacecraft instrumentation are not always considered ideal. Pointing the instrument at some dark object is a common alternative but the actual darkness of the object is questionable. Dark Earth may not be so dark at certain altitudes and latitudes. In fact, it may be brighter than the sky due to various electromagnetic or particle induced emissions in the UV.

This atmospheric emission—another source of diffuse radiation—must be fully understood when observing from an Earth orbiting platform. There are at least 20 known or suspected UV line and band emission features in the Earth's airglow and aurora. Particle induced emissions are probably the most

treacherous of these sources because of their intensity and uncertain spatial and temporal variation over the Earth's surface. This source is not restricted to the auroral zones, but may appear almost anywhere at any time, including the equatorial regions due to ring current precipitation<sup>2,3</sup>. It is essential to exclude at least the most intense emission lines from the instrument's bandpass. However, this may not be a sufficient precaution as weak band emissions throughout the far UV may contribute to a broad band observation<sup>4</sup>.

A more drastic solution would be to escape the Earth's atmosphere and observe from a platform in the interplanetary medium. However, even this medium is a source of diffuse UV radiation. In this case, scattering of solar light by zodiacal dust grains and by atomic and singly ionized interstellar gas atoms must be considered. The former source of emission is probably not important below about 2,000 Å (refs 5, 6) but becomes troublesome just above this wavelength. At an elongation of 30° on the ecliptic plane, the zodiacal light intensity at 2,000 Å may reach  $\approx 500$  photons  $\text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{Å}^{-1}$ , a value uncomfortably close to the observed cosmic background intensities plotted in Fig. 1. Any correction for this effect should include systematic exploration of the ecliptic plane at many elongations and observations as far removed from this plane as possible.

Backscattered UV line radiation at the resonance transitions of interstellar hydrogen and helium flowing into the interplanetary medium because of the large relative motion of the Solar System with respect to the interstellar medium is also of considerable importance<sup>7</sup>. Observed emissions include the H I 1,216 Å and 1,026 Å and the He I, 584 Å resonance lines with suspected weaker contributions from He II 304 Å, He I 537 Å, N II 1,085 Å, O I 1,304 Å, and C II 1,336 Å that have the necessary corresponding exciting lines in the solar spectrum. These emission lines influence UV observations by their strength (especially Ly $\alpha$  at  $\approx 3 \times 10^8$  photons  $\text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1}$ ) and seasonal variability.

### Point sources

Progress in understanding point sources of UV emission critically influences the results of the UV background observations because some of these sources will be in the field of view of an instrument attempting to measure the diffuse background. The best way of correcting for stellar contamination is to use the TD1 catalogue of stellar UV fluxes<sup>8</sup> covering the range 1,500–2,500 Å down to  $m_v \approx 8-9$ , supplemented, where possible, by the corresponding spectrophotometric catalogue<sup>9,10</sup>. For this technique to be accurate enough, the instrument response and

\* Permanent address: Copenhagen University Observatory.

the field of view must be well known, preferably by means of careful in-flight calibrations.

For fainter stars or for  $\lambda < 1,500 \text{ \AA}$  we have to use theoretical models for the stellar emission and luminosity functions for hot stars obtained in the optical band; large errors are, therefore, to be expected.

Henry<sup>11</sup> has described a technique to overcome some of these problems in which stars in the SAO catalogue are integrated in conjunction with a UV stellar calibration<sup>12</sup>. Although simple, this method may overestimate the stellar contribution due to errors in the listed spectral types and the lack of a suitable correction for differential interstellar dust extinction.

A simpler method, in principle, is to reduce the instrument field of view to a size such that the number of stars having a certain limiting magnitude becomes very small. This limiting magnitude has been estimated for observations at  $1,500 \text{ \AA}$  to be near  $m_v = 9.5-10$  (ref. 11). This is effective provided the collecting area of the telescope rises simultaneously as the square root of the decrease in the field of view to maintain the same signal-to-noise ratio: this may become impractical or too expensive. As a rule, with recent technology, a 1-m diameter telescope is necessary to achieve a sensitivity slightly below that needed to detect the lowest observed UV intensity ( $\approx 300 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ \AA}^{-1}$  at  $1,500 \text{ \AA}$ ) with a 15–20 arc min field of view.

An added advantage can be envisaged by restricting one's background observations to high galactic latitudes where hot stars are few and far between. This works well for O and B stars, is dubious for A stars and of no use for F and later stars. Because A stars (especially A0 stars) contribute substantially to the background above  $1,500 \text{ \AA}$  (ref. 11), this technique is best suited to observations in the range  $\approx 1,000-2,000 \text{ \AA}$ .

After these precautions, there remains the important question of the residual faint ( $m_v > 10$ ) star distribution and the possible magnitude of its contribution to the observed UV background. We have estimated this contribution using standard main sequence colours, absolute visual magnitudes, scale heights and luminosity functions. Conversion to the UV is accomplished by using observed mean  $(m_v - m_\lambda)_0$  versus  $(B - V)_0$  relations<sup>12,13</sup>, with the result that the contribution due to the sum of all main sequence stars of  $m_v > 10$  in the Galaxy at  $1,500 \text{ \AA}$  in the direction of the galactic poles cannot exceed  $30 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ \AA}^{-1}$ .

Not all hot stars, however, can be assumed to be on the main sequence. Green<sup>14</sup> has shown that hot white dwarfs comprise  $\approx 64\%$  of the known faint blue star population down to a  $B$  mag of  $\approx 16$ . Using his derived luminosity function and scale height for these objects and assuming that all the hot white dwarfs in his sample are as hot as HZ43, one of the hottest white dwarfs known<sup>15</sup> we can calculate a strict upper limit to their effect on an UV background measurement. We find that their contribution at the poles and at  $1,500 \text{ \AA}$  cannot exceed  $\approx 20 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ \AA}^{-1}$ . Other possible sources of stellar UV radiation such as subdwarf OB stars and blue horizontal branch stars are probably too scarce in space to give a substantial contribution<sup>16</sup>. Thus with the accuracy allowed by the input astronomical data, unresolved faint stars will contribute  $< 50 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ \AA}^{-1}$  at  $1,500 \text{ \AA}$  in the direction of the galactic poles.

## Observations

All observers have to deal with at least some of the above problems to claim a measurement of a truly cosmic (galactic or extragalactic) background. Henry *et al.*<sup>17</sup>, using a rocket-borne  $10^\circ \times 10^\circ$  Geiger counter sensitive to the  $1,425-1,640 \text{ \AA}$  range, mapped the entire sky observable in March from White Sands, New Mexico. After in flight calibrations and subtraction of the average count rate observed when the detector was pointed  $25^\circ$  or more below the horizon were performed, the residual signal was compared with the signal expected from the integration of the stars in the SAO catalogue. The data for  $b < 45^\circ$  are reasonably well accounted for by the predictions but a large observational excess is evident in the range  $b > 45^\circ$ . At high galactic latitudes Henry *et al.* find the intensity of the UV background corrected for stellar contributions to be in the range  $1,000-1,900 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ \AA}^{-1}$ . The high galactic latitude measurement is displayed in Fig. 1 where we have plotted the observed background intensity in units of  $\text{eV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ eV}^{-1}$  as a function of wavelength in  $\text{\AA}$  for each measurement discussed here. According to Henry *et al.*, the reported excess is due to airglow in the  $1,425-1,640 \text{ \AA}$  band and one may hypothesize the presence of weak emissions of  $\text{N}_2$  in the Lyman-Birge-Hopfield bands<sup>4</sup> as a possible source of this contamination.

**Fig. 1** Observations and theoretical estimates of the diffuse UV background at high galactic latitudes as a function of wavelength (delete  $\text{eV}^{-1}$  for the interplanetary lines). Sources of the observations: A, ref. 22; H, ref. 17;  $\diamond$ , ref. 18; M, refs 24, 28;  $\triangle$ , ref. 29; P, refs 25, 26;  $\circ$ , ref. 34;  $\square$ , ref. 23; S, ref. 31;  $\odot$ , ref. 35.

Lillie and Witt<sup>18</sup> used the Wisconsin Experiment Package  $10 \times 10$  arc min broadband photometers on OAO 2 to study the intensity, spectrum and spatial distribution of the UV background between 1,550 and 4,250 Å. Their results are summarized in Fig. 1 which displays their average intensities in the  $40^\circ < b < 90^\circ$  range. Their  $S_{10}$  units are converted to our physical units using the TD1 spectrum of  $\alpha$  Lyr<sup>9</sup>. These results supersede the earlier published observations from OAO 2 (ref. 19) because of their superior accuracy, spatial coverage and signal-to-noise ratio.

The OAO 2 measurements plotted in Fig. 1 are corrected for instrumental background using mechanically actuated shutters, for zodiacal light by means of an empirical correction formula incorporating several observational results and for light of stars of  $m_v > 11.5$  by optical photoelectric drift scanning of the observational fields. For the reasons outlined above we would expect the most accurate numbers in this case to be those corresponding to the shortest wavelengths and to the highest galactic latitude range observed. In this case, however, the weakness of the signals in the very small OAO field of view at high galactic latitudes introduces a substantial observational error that may approach 100% of the observed signal in some cases. The fact that the adopted zodiacal light spectrum below 2,000 Å (ref. 20) may be too high<sup>6</sup> probably has very little influence on the results because of the vanishing solar flux at 1,500 Å.

With a  $12^\circ \times 12^\circ$  scanning spectrometer sensitive to the 1,180–1,680 Å range, Henry *et al.*<sup>21</sup> observed the sky near the south and north galactic poles from Apollo 17 on trans-Earth coast, free from the effects of the terrestrial atmosphere. The resulting UV background spectrum consisted of a wide emission feature centred at 1,450 Å, of maximum intensity  $\approx 250$  photons  $\text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{Å}^{-1}$  and with little or no emission at 1,250 and 1,650 Å. Unfortunately, a large and complex correction for instrumental background, starlight and Ly $\alpha$  scattering in the instrument amounting to  $\approx 85\%$  of the signal significantly reduces the confidence level of the result.

In a repeat experiment performed from a rocket by Anderson *et al.*<sup>22</sup>, the 1,450 Å 'feature' at the galactic pole disappears and is replaced by a featureless constant background of  $\approx 285$  photons  $\text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{Å}^{-1}$  between 1,250 and 1,650 Å. A suggestion of a ledge or discontinuity at  $\approx 1,650$  Å is found in this experiment which, because of its smaller field of view ( $1.4^\circ \times 5.8^\circ$ ) is less susceptible to large starlight subtraction errors. The outer envelope of the spectrometer results from this experiment is plotted in Fig. 1 rather than the results from Apollo 17 as the latter are far more uncertain and highly discrepant with the rocket results at 1,250 and 1,650 Å. The former should be considered essentially free of the problems encountered by the Apollo 17 experiment because the instrumental background was low, a crystal filter shielded the Instrument from Ly $\alpha$  radiation and the stellar correction for two of the three targets observed was quite small. From the results on these three targets, Anderson *et al.* suggest that the UV background is spatially uniform at this intensity.

A three channel UV polychromator with a  $2^\circ$  circular field of view flown on a rocket by Pitz *et al.*<sup>23</sup> measured the UV sky brightness at 1,800, 2,200 and 2,600 Å. After the data were purged of instrumental effects and corrected for airglow and zodiacal light and starlight contaminations, the intensities for  $b = 60^\circ$  displayed in Fig. 1 were reported. The quasi twilight observing configuration (solar zenith angle  $\sim 110^\circ$ ) makes correction for airglow risky. Pitz *et al.*<sup>23</sup> claim that the brightness distribution with view direction is uniform but it is not clear at what level of accuracy. Only a few observations at different latitudes are reported—the result of an extensive averaging procedure that might easily mask a more pronounced spatial variation.

A similar difficulty of interpretation is encountered with data of Maucherat-Joubert *et al.*<sup>24</sup> obtained from the ELZ photometer on board the D2B satellite. This experiment consisted of a  $1.3^\circ \times 1^\circ$  objective grating-photomultiplier detector

combination sensitive to the 1,525–1,855 Å range surveying the entire sky from a 600-km altitude orbit. The outer envelope of the validity range of their results for  $b > 40^\circ$  is shown in Fig. 1. Because of the altitude of the satellite, the wavelength band, the small field of view and the observing configurations, airglow, zodiacal light and starlight probably form a small part of the observed signals after elimination of the bright star fields ( $m_v > 8$ ). Because the instrumental background was high and difficult to assess properly, the data was averaged over relatively large spatial zones, thereby losing possible spatial information. As the observed range of intensities was much wider than expected from counting statistics alone, an additional source of emission was invoked. Faint stars with the true UV background consequently uniform were suggested in accordance with the results of Anderson *et al.* and Pitz *et al.* Another possibility is that the spread is due to an actual spatial variation of the UV background itself.

The latter conclusion would be more compatible with the results of the survey carried out with the  $2.5^\circ$  field of view telescope on board the Apollo-Soyuz Test Project (ASTP). A patchy spatial distribution of the UV background is reported<sup>25,26</sup> with intensities ranging from a sharp minimum of 300 to  $\approx 4,000$  photons  $\text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{Å}^{-1}$  after correction for stars of  $m_v \leq 9-10$ , instrument background and airglow. The latter corrections were made using a moveable shutter and observation of the Earth from the 225 km altitude of the spacecraft. The range of intensities observed for  $b > 40^\circ$  is also shown in Fig. 1 at the appropriate wavelength band.

There are two obvious explanations for the radiation pattern observed: (1) diffuse radiation scattered by galactic dust or (2) random airglow contamination not accounted for by the Earth pointed observations and not satisfying the standard rules to airglow phenomenology<sup>27</sup>. The latter explanation of the discrepancy between the Paresce *et al.* results and those of Anderson *et al.* is the simplest because, for at least two of the Anderson *et al.* targets, there corresponds an ASTP observation made in essentially identical conditions and yielding a factor of  $\approx 3$  difference in intensities. However, the clear correlation found<sup>26</sup> between the ASTP UV background intensity and galactic N (H I) column density as determined by 21-cm radio observations suggests a galactic origin of a good part of the observed signal.

This result has been confirmed by Maucherat-Joubert *et al.*<sup>28</sup> after a reanalysis of the D2B data. They constructed histograms of individual count rates corresponding to areas in the sky of 24–40 square degrees, regions much smaller than those considered in the original analysis. After removal of resolved stars, subtraction of dark current and zodiacal light, a reasonably good correlation between observed 1,690 Å intensity and N (H I) is found for all view directions corresponding to  $b > 40^\circ$ . The large scatter in the correlation may be partly due to variations in galactic plane brightness and dust-to-gas ratio from point to point in the sky<sup>26</sup>.

Further analysis<sup>28</sup> of the UV background with the ELZ instrument at 2,200 and 3,100 Å is reproduced in Fig. 1. The similarity in shape of the UV background spectrum towards the poles and towards the Coal Sack nebula has been used to favour the scattered galactic light hypothesis.

Morgan *et al.*<sup>29,30</sup> have reported TD-1 measurements of the UV background. Unfortunately, because of substantial airglow contamination (especially Ly $\alpha$ ) of uncertain magnitude, only the variation of the signal with galactic latitude could be ascertained with any accuracy. Thus these results have limited value except to confirm that the albedo of interstellar grains is  $\sim 0.5$  in the 1,550–2,740 Å range and to set an upper limit to the UV background at 2,740 Å which is shown in Fig. 1.

The UV spectrometer on the Voyager spacecraft<sup>31</sup> has the capability of measuring the UV background in the 500–1,700 Å region with  $\approx 10$  Å wavelength and  $0.9^\circ \times 0.1^\circ$  spatial resolution with high sensitivity due to the long observing times available and the absence of terrestrial airglow contamination. Large instrumental backgrounds, uncertain corrections for Ly $\alpha$

interplanetary emission and uncertainties in instrument calibration still hamper attainment of the ultimate instrument sensitivity to weak diffuse fluxes.

These problems necessitate subtracting a background spectrum obtained in one view direction and used as a 'scattering background spectrum' from a spectrum obtained in another direction as was done in the Voyager results analysis. Hence spatial variations conveying basic physical facts concerning the radiation field may be obliterated. The outer envelope of the results of this experiment are shown in Fig. 1. The generally higher values may, in part, be due to the generally lower galactic latitudes ( $b < 40^\circ$ ) of the Voyager view directions than for the other measurements displayed in Fig. 1 which generally pertain to the  $b > 40^\circ$  region.

The spectral feature at  $\approx 1,450 \text{ \AA}$ , first detected by Henry *et al.*<sup>21</sup> and not confirmed by Anderson *et al.*<sup>22</sup>, is also reported by Hua *et al.*<sup>32</sup> but of varying intensity in the two places in the sky observed. This experiment consisted of a  $53 \text{ \AA}$  resolution,  $6^\circ \times 6^\circ$  field of view scanning spectrometer sensitive to the  $1,100\text{--}1,900 \text{ \AA}$  region flown on the Prognost-6 satellite. Because calibration of the instrument is uncertain it is premature to give it the same weight as the other measurements shown in Fig. 1.

The UV background is almost certainly made up of components displaying widely different physical characteristics in the emitted radiation field including different intensities, spatial variations and polarization at different wavelengths. Attempts to unify these properties into a diagram similar to Fig. 1 will probably turn out to be an oversimplification. Because of our limited knowledge, however, it is useful for gaining a general perspective on the problem that would be difficult if we were restricted to a small subset of the UV spectrum. It also ensures that any postulated source of UV radiation does not violate observational limits in the adjacent spectral regions. For these reasons we have expanded the scale of Fig. 1 to include the EUV on one end, the visible on the other, and have included results pertaining to different phenomena that must be present whenever a measurement of the UV background is attempted. It also vividly displays the variety of physical emission mechanisms operating in the UV and the information one can obtain concerning the structure of the interstellar gas and dust components.

Figure 1 thus includes observations of the EUV background in the  $50\text{--}600 \text{ \AA}$  wavelength region<sup>33,34</sup>, the range of observed intensities of the diffuse interplanetary emission lines at  $304$ ,  $584$ ,  $1,026$  and  $1,216 \text{ \AA}$  and the limit on the night sky background at  $4,150 \text{ \AA}$  (ref. 35). Although the scatter, individually and collectively, of the data is large, there seems to be remarkable agreement over a wide range of wavelengths from the visible to the beginning of the EUV that the UV background is relatively constant between  $10^6$  and  $10^7 \text{ eV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ eV}^{-1}$  at high galactic latitudes. The largest deviations occur in the far UV ( $1,000\text{--}2,000 \text{ \AA}$ ) where most observations are concentrated. It is not yet possible to decide whether the large scatter at these wavelengths reflects reality or is due to the observational problems discussed above. If the scatter is real and due to variations in observing direction and wavelengths, for example, the relative lack of such scatter at wavelengths longer than  $2,000 \text{ \AA}$  may simply be fortuitous and due to the much smaller number of observations available. The most difficult region of observation is at  $\lambda > 2,000 \text{ \AA}$  where the effects of zodiacal light and starlight contamination become severe.

Below  $1,000 \text{ \AA}$  observations become extremely difficult both because of the insensitivity of presently available EUV instrumentation<sup>36</sup> and the large interstellar H I absorption cross-section below  $912 \text{ \AA}$  (ref. 37). A large gap in our knowledge of the UV background between  $300$  and  $1,000 \text{ \AA}$  is due to these difficulties and more local interplanetary line emission phenomena dominate the EUV at present. After a drop of  $\sim 3$  orders of magnitude, the background due to hot ( $T > 10^5 \text{ K}$ ) gas in the galaxy as attenuated by intervening H I, perhaps the same gas responsible for the O VI absorption feature in hot stars<sup>38</sup>, is probably the dominant diffuse emission mechanism in the EUV.

## Diffuse galactic light

Interstellar dust particles may scatter starlight that was initially travelling out of the Galaxy back to an observer in the plane. The intensity of this reflected radiation at a specific wavelength  $\lambda$  will depend on the albedo,  $a(\lambda)$ , the phase function asymmetry factor,  $g(\lambda)$ , the optical depth of the dust and the galactic disk, and the source function of starlight. Davidsen *et al.*, using then standard dust models, estimated the brightness of this source at the poles to be  $\approx 250 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ \AA}^{-1}$  at  $1,400 \text{ \AA}$ , quite a large amount if the expected extragalactic contribution is much fainter. A convenient solution to this problem was suggested by Sandage's observations of  $E(B - V) = 0$  for  $b > 50^\circ$  (ref. 39). There is now considerable doubt about the validity of this result. Sandage<sup>40</sup> was, in fact, the first to discover faint filamentary structured reflection nebulae in the visible at latitudes as high as  $|b| \approx 50^\circ$ . The brightest of these filaments have an optical extinction as high as  $A_v \sim 0.3 \text{ mag}$  and are clearly visible on the Sky Survey Palomar prints where they can be traced to regions not covered by Sandage's work. These clouds possibly cover a large part of the sky around the galactic poles. Recent measurements of polarization and reddening of high-latitude stars<sup>41-43</sup> give further evidence of the existence of dust near the galactic poles.

An H I column density of at least  $2 \times 10^{20} \text{ cm}^{-2}$  at the poles<sup>44</sup>, and the canonical dust-to-gas ratio<sup>45-47</sup>, recently extended to the poles by Knude<sup>43</sup> ensure that  $E(B - V) > 0.03$ , and it seems safe to claim that  $0.03 < E(B - V) < 0.3$  for  $|b| > 50^\circ$ . This result implies that dust could be a source of diffuse galactic radiation, but its presence alone is not a sufficient condition for this effect to be noticeable as the scattered intensity is also very sensitive to the values of  $a(\lambda)$  and  $g(\lambda)$ . As far as the albedo of the dust is concerned, there seems to be general acceptance of values near  $a \approx 0.5$  for  $\lambda > 1,400 \text{ \AA}$ , which is consistent with a recent model of the interstellar grains<sup>48,49</sup>. The value of the parameter  $g$ , is, however, a subject of some controversy. Henry *et al.*<sup>50</sup> argued for values of  $g$  higher than  $0.9$ , implying that the interstellar dust is strongly forward scattering, whereas others<sup>51-53</sup> argued for much lower values, that is,  $g \approx 0.2$ , or much more isotropically scattering dust grains. The above dust model predicts an intermediate value of  $g \approx 0.6$  at UV wavelengths which agrees well with previously<sup>26</sup> derived value on the basis of a comparison with Jura's predictions<sup>53</sup> and with recent TD-1 observations of UV radiation around  $\lambda \text{ Ori}$  (ref. 54).

The patchiness of the background radiation at  $1,450 \text{ \AA}$  and the reported correlation<sup>26,28</sup> with hydrogen column density does indeed suggest that backscattered galactic disk starlight is an important contributor to the diffuse background at UV wavelengths. The question then arises of whether the general level of the measured background is compatible with this view. This problem has been discussed by Jura<sup>53,55</sup>.

An uncertainty in calculating the amount of backscattered starlight lies in estimating the intensity of the radiation incident on the high latitude dust. As the reflecting material is essentially seeing the Milky Way from well above the galactic plane, this problem is connected with the general question of the amount of UV radiation emerging from spiral galaxies. The curve 'Reflection nebulae' in Fig. 1 gives the predicted UV surface brightness of the densest of Sandage's filaments placed at  $b \sim 90^\circ$  as a function of wavelength, calculated in terms of Jura's reflection nebula model<sup>55</sup> and assuming the White<sup>49</sup> model for interstellar dust. The incident radiation was determined by using a value of  $A_v \sim 0.3 \text{ mag}$  for the optical depth of the galactic disk and by assuming that the Milky Way as seen from outside the galactic plane has the same UV spectrum as the spiral galaxies observed with the OAO 2 satellite<sup>56</sup>. The magnitude of the UV radiation field was determined by normalizing to the total local radiation density at  $1,450 \text{ \AA}$  observed onboard Apollo-Soyuz<sup>26</sup>.

In spite of all the uncertainties, the general level of the theoretically expected backscattered light is in rough accord with the observed background level throughout the far UV into the visible. Note that the calculation refers to the very brightest filaments observed, and that Sandage reported filamentary

structure on scales from arc minutes to several degrees. Because most measurements are performed with instruments having fields of view larger than this, the observed smeared out background could be lower in those cases. However, the order of magnitude agreement between predictions and observations supports the claim that backscattered starlight is an important source of background light and an obstacle that must be overcome before the true extragalactic component of the UV background can be determined.

The possibility of large amounts of reflecting material existing at high galactic latitudes could limit the performance of the Space Telescope at short wavelengths but the patchiness of the filaments as indicated by Sandage and the Apollo-Soyuz data, suggests we may find rifts in the interstellar cloud cover through which it may be possible to catch unobstructed glimpses of extragalactic sources in the UV.

## Extragalactic sources

The background light due to distant galaxies and quasars arises as the emission from all objects along a given line of sight looking out into the Universe. But because of redshift and lookback-time effects, more distant sources contribute to the background at a given wavelength today with light emitted at earlier epochs at shorter wavelengths. In a Friedman Universe with Hubble constant  $H_0$  and density parameter  $\Omega$ , the background intensity  $I_{\lambda_0}$  at wavelength  $\lambda_0$  due to a class of objects with luminosity density  $\epsilon_{\lambda_0}$  can be written<sup>57</sup>

$$I_{\lambda_0} = \left( \frac{c}{H_0} \right) \frac{\epsilon_{\lambda_0}}{4\pi} A_{\lambda_0}$$

with  $A_{\lambda_0}$ , 'the accumulation factor' given by

$$A_{\lambda_0} = \int_0^\infty \chi_\lambda(z, \lambda_0/(1+z)) \phi(z) (1+z)^{-4} (1+\Omega z)^{-1/2} dz$$

$\chi_\lambda(z, \lambda)$  describes the mean spectra and  $\phi(z)$  the comoving density evolution of the objects under consideration, both normalized to  $\chi_\lambda(0, \lambda_0) = 1$  and  $\phi(0) = 1$ .

To estimate the expected UV background due to galaxies and QSOs, detailed information on the UV spectra and evolution of these objects is required. Conversely, measurements of the background radiation field can, in principle, constrain different galaxy and quasar evolution hypotheses.

Despite recent advances in space borne instrumentation, surprisingly little is known about the UV spectra of galaxies. This is mainly because the instruments that have been launched up until now have been of moderate size and optimized for stellar work. For example, IUE galaxy observations have been restricted to spectra of the central regions of elliptical galaxies and bulge components of spirals, that is of portions of objects with large surface brightness. The spectra of these regions fall off rapidly shortwards of the *B*-band at  $\sim 4,400 \text{ \AA}$  down to  $\sim 2,000 \text{ \AA}$  after which a relatively flat residual remains at a level of  $f_\lambda \sim 0.05 f_\lambda(B)$  (refs 58, 59). The origin of the far UV galactic radiation is controversial but if this behaviour is assumed typical of all galaxies, the expected galaxy background contribution, neglecting evolution and calculated for  $\Omega = 0$ , is plotted as the curve 'Galaxies/1' in Fig. 1. Note that there is an overall uncertainty in all calculations of this type of a factor  $\sim 2$  due to the uncertainty in the total *B*-luminosity density in galaxies alone, but that the calculations are otherwise insensitive to the cosmological model.

In the other extreme case one can, following Anderson *et al.*<sup>22</sup>, adopt as the typical galaxy spectrum the mean Scd galaxy spectrum<sup>56</sup> observed with OAO 2, extrapolated to the Lyman limit. The expected background contribution in this case, neglecting evolution, is shown as the curve 'Galaxies/2' in Fig. 1.

Thus if all galaxies have as energetic short wavelength spectra as the Scd galaxies observed by the OAO 2, and our extrapolation to the Lyman limit is valid, the integrated light from distant galaxies could be a substantial contributor to the UV background light.

Because all galaxies are not spirals, the true galaxy background is probably between the two cases shown in Fig. 1. Recent estimates of the colour distribution of galaxies<sup>60,61</sup>, suggest that only about 5–10% of the total *B*-light from galaxies is emitted by ellipticals, implying that the latter estimate is perhaps the most realistic. Tinsley<sup>62</sup> showed that the accumulated galaxy radiation at visible wavelengths is very sensitive to the effects of galaxy evolution, but the situation in the far UV may be less complicated<sup>63</sup>. This is because the short wavelength light emitted by spiral galaxies originates almost entirely from the young, short-lived *O* and *B* star population continuously forming in the spiral arms. Aside from the disturbing effects of dust absorption, the intensity and slope of the far UV spectrum of a spiral galaxy at a given epoch directly mirror the rate of formation and the initial mass function of the young hot star population. If, for example, the initial mass function is independent of epoch and the rate of star formation decreases exponentially with the galaxy age, this will give rise to an exponential increase in the overall far-UV luminosity of spiral galaxies with look back time<sup>64</sup>. In this way, the background measurements shortward of  $2,000 \text{ \AA}$  together with the adopted OAO 2 spiral spectrum set a rough lower limit on the e-folding time for stellar formation of about a quarter of the Hubble time or  $\approx 5,000 \text{ Myr}$ . Taking such evolution effects into account will raise our background estimate  $\sim 50\%$  shortwards of  $2,000 \text{ \AA}$ , making galaxies even more important contributors to the UV background.

Results from the HEAO 2 satellite concerning the contribution to the X-ray background from quasars<sup>65</sup>, suggest that these objects might be expected to also play an important part in generating the background at UV wavelengths. Adopting the estimated QSO-luminosity function<sup>66</sup> and  $\phi(z) = e^{10z/(1+z)}$  density evolution<sup>67</sup> together with a  $\chi_\lambda \propto \lambda^{-1}$  powerlaw spectrum extending unattenuated beyond the Lyman limit, the expected background is shown as the curve 'Quasars' in Fig. 1. A quasar turn on epoch of  $z \sim 3$  was assumed, but with the adopted density evolution, the result is not very sensitive to the exact redshift at which QSOs first appear. Although the predicted background falls far below the UV measurements, it is interesting that the integrated light from quasars does exceed the EUV background in Fig. 1. Because this radiation is reasonably well accounted for by hot interstellar gas emission<sup>34</sup>, this suggests that QSOs are less bright at soft X-ray energies than expected from an extrapolation of the  $\chi_\lambda \propto \lambda^{-1}$  continuum observed in the optical, either because of intrinsic shielding or because of a true steepening of the continuum<sup>68</sup>.

Although the integrated light from quasars seems unimportant in connection with the UV background, a large fraction of the QSO radiation is emitted at wavelengths shortwards of the Lyman limit at distant epochs and may play an important part in photoionizing the mythical intergalactic medium.

Although most cosmological information suggests that the Universe is open by a large margin<sup>69,70</sup> and that the major fraction of matter in the Universe is in the form of galaxies, many attempts have been made to detect a dense intergalactic medium (IGM).

Whereas the observed X-ray background could arise as emission from a very hot ( $T \approx 10^8 \text{ K}$ ) IGM<sup>71,72</sup>, the intensity of the background at UV wavelengths is relevant in the case of a "lukewarm" or photoionized IGM with a temperature between  $\approx 10^3 \text{ K}$  and  $\approx 10^5 \text{ K}$ . Several IGM models which predict temperatures in this range, at least at some epoch, have been proposed<sup>73–77</sup>. This case has been discussed recently in terms of the resulting background radiation<sup>26,57</sup>.

At temperatures  $10^3 < T < 10^5 \text{ K}$  a mixture of hydrogen and 10% helium radiates strongly in the two resonance lines of H I at  $1,216 \text{ \AA}$  and He II at  $304 \text{ \AA}$ . This line emission, smeared by the redshift, should turn up as background radiation in the UV. The two more or less complementary mechanisms for generating such line radiation are (1) collisional excitation which dominates in an IGM heated by dissipative processes; and (2) recombination which dominates in a highly photoionized medium.

Although the emissivity in the collisional excitation case is in general much larger than in the recombination case, very specific conditions, that is a combination of incomplete ionization and high electron temperatures, are necessary to maintain this large emissivity and corresponding high level of background radiation.

Very strict upper limits on the possible amounts of dense, well-distributed intergalactic neutral hydrogen are set by the lack of strong absorption troughs between emitted and observer frame Ly $\alpha$  in the spectrum of high redshift quasars<sup>78</sup>. It follows that if a dense IGM does exist, the intergalactic hydrogen must be highly ionized, typically to a level of 1 p.p.m. This severely constrains all IGM models and reduces the chances of detecting the IGM in emission by excluding the case for a  $T \approx 2 \times 10^4$  K IGM radiating strongly in Ly $\alpha$  by collisional excitation.

The curve 'Ly $\alpha$ ' in Fig. 1 shows the expected background contribution due to redshifted recombination Ly $\alpha$  from a dense, fully ionized IGM of temperature  $10^4$  K, having a closure density appropriate for a Hubble constant of  $50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ . The expected background intensity increases at longer wavelengths corresponding to emission from earlier, more dense, epochs as the recombination emissivity is proportional to density squared. This estimate scales with cosmological parameters as  $\Omega_b^2 h_{50}^3$ , where  $\Omega_b$  denotes the IGM density in units of the critical density and  $h_{50}$  the Hubble constant in units of  $50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ .

Regarding redshifted He II 304 Å line radiation, there is no direct information on the ionization of intergalactic helium, but the Space Telescope will make it possible to carry out the He I 584 Å and He II 304 Å equivalents of the Gunn-Peterson test<sup>68</sup>, and set upper limits on the concentrations of neutral and once ionized intergalactic helium. Until then it cannot be completely excluded that the IGM at some epoch has gone through a phase of intense collisional excitation generated He II 304 Å emission as predicted by some IGM-reheating models<sup>74,76</sup>. Although the reported 1,450 Å background feature<sup>21,32</sup> is suggestive of such radiation, its existence is in doubt. In any case, at 1,450 Å the observations<sup>22,25,26</sup> can be used to set a rigorous upper limit to an extragalactic component of  $300 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ Å}^{-1}$ .

The curve 'He II 304' in Fig. 1 shows the expected background due to redshifted He II 304 Å recombination radiation from a fully ionized IGM calculated for a temperature of  $10^4$  K and the combination  $\Omega_b^2 h_{50}^3 = 1$ . The He II 304 Å emissivity in the collisional excitation case with these parameters is, at most, a factor  $\approx 5$  higher than that of the recombination case, still giving a background well below the measurements.

The measured intensities of the UV background do not set very interesting limits on the density of a photoionized intergalactic medium in terms of redshifted IGM recombination emission ( $\Omega_b^2 h_{50}^3 \leq 280$  from Ly $\alpha$  and  $\Omega_b^2 h_{50}^3 \leq 70$  from He II 304 Å). A more interesting constraint is that, as any existing IGM must be highly transparent according to the Gunn-Peterson test, the ionizing flux that maintains the implied high level of ionization must turn up as background radiation at the appropriate wavelengths. The curve 'Photoionized IGM' in Fig. 1 shows the background level produced by the redshifted Lyman continuum radiation necessary to photoionize a dense intergalactic medium to the required level. This curve also scales with cosmological parameters as  $\Omega_b^2 h_{50}^3$ , so even assuming that the lowest background measurement at 1,450 Å of  $300 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ Å}^{-1}$  consists of the sum of contributions from redshifted recombination Ly $\alpha$  from  $z = 0.2$ , redshifted Lyman continuum radiation from  $z = 0.6$  and redshifted recombination He II 304 Å radiation from  $z = 3.8$  leads to the inequality  $\Omega_b^2 h_{50}^3 \leq 10$ , leaving a wide margin for a closed universe in the dense photoionized IGM picture. We cannot rigorously exclude that a major portion of the UV background radiation is redshifted Lyman continuum radiation, but this interpretation seems unlikely because no known sources, quasars included, seem capable of producing such a large ionizing flux.

The discussion above refers to a dense well-distributed intergalactic medium. On the other hand a very plausible interpretation of the numerous absorption lines seen shortwards of

emitted Ly $\alpha$  in the spectra of high redshift quasars is that at least some of these lines arise as Ly $\alpha$  absorption in intervening intergalactic clouds<sup>79-81</sup>.

Taking clumping into account increases the IGM emissivity by the 'clumping factor',  $C(z) = \langle n^2 \rangle / \langle n \rangle^2$ , but the redshifted line radiation decreases in intensity towards longer wavelengths because the clumping is expected to increase with time at least as  $C(z) \propto (1+z)^{-3} \propto \lambda^{-3}$ , corresponding to comoving clouds of fixed dimensions<sup>26</sup>. As an example, curves 'Ly $\alpha$ /C' and 'He II 304/C' show the expected redshifted Ly $\alpha$  and He II 304 Å background from unevolving photoionized intergalactic clouds, for simplicity calculated for  $\Omega_b^2 h_{50}^3 C(0) = 1$ . Sargent *et al.*<sup>81</sup> presented a homogeneous sample of QSO Ly $\alpha$  absorption lines observed in high resolution spectra of six quasars. Unfortunately, the interpretation of these spectra in terms of the physical parameters of the absorbing matter is not unique. However, Sargent *et al.*<sup>81</sup> proposed a low density IGM photoionized by quasars consisting of clouds of density  $\sim 10^{-4} \text{ cm}^{-3}$  and temperature  $T \sim 3 \times 10^4$  K embedded in a medium with a density  $\sim 10^{-5} \text{ cm}^{-3}$  and temperature  $\sim 3 \times 10^5$  K (at redshift  $z \sim 2.5$ ). If so, the expected background due to IGM emission is very low, as these parameters translate to  $\Omega_b^2 h_{50}^3 C(0) \approx 10^{-1}$  for the intergalactic clouds giving rise to the QSO absorption lines and  $\Omega_b^2 h_{50}^3 \approx 10^{-2}$  for the surrounding medium. As far as the background radiation is concerned, the above is mainly interesting in that the true integrated light from quasars must be similar to that given in Fig. 1 for these objects to supply sufficient Lyman continuum radiation to photoionize the intergalactic clouds to the required level.

The expected level of IGM emission under reasonable assumptions is far below the measured UV background intensity. The present measurements do not rule out a dense photoionized IGM, but future observations with higher sensitivity together with a better understanding of the other background contributions should place interesting limits on this possibility.

## The interstellar radiation density

UV photons have sufficient energy to ionize, dissociate and heat the interstellar medium<sup>82-84</sup>. The heating effect of UV photons on diffuse clouds and the periphery of larger clouds is quite important. For example, the proposed heating mechanisms of diffuse interstellar clouds require UV photons to photoeject electrons from grains<sup>85,86</sup> or to excite H<sub>2</sub> to vibrationally bound levels<sup>87</sup>. Absorption of UV radiation by H<sub>2</sub> controls the abundance of this and other molecules in cool clouds<sup>88</sup>.

Most of the UV radiation in the solar neighbourhood probably originates in O and B stars<sup>88-90</sup> and hot white dwarfs<sup>14</sup> within 1 kpc of the Sun. Just below the H I ionization threshold at 912 Å, the mean free path of UV photons is small<sup>37</sup> and the radiation field is characteristic of a smaller region around the

**Fig. 2** Observations and theoretical estimates of the interstellar radiation density as a function of wavelength. Sources of the observations:  $\square$ , ref. 17;  $\otimes$ , ref. 26;  $\triangle$ , ref. 97. Sources of the calculations:  $\square$ , ref. 98;  $\bullet$ — $\bullet$ , ref. 99; —, ref. 89;  $\boxtimes$ , ref. 96; —, ref. 11;  $\diamond$ , ref. 88;  $\circ$ , ref. 100;  $\nabla$ , ref. 101;  $\triangle$ , ref. 102;  $\bullet$ — $\bullet$ , ref. 97.

Sun out to  $\approx 10$  pc or so. The field in this case will be dominated by the combined effects of the  $\approx 10$  early type B stars to be found at these distances from the Sun<sup>91</sup> and hot white dwarfs, subdwarfs, novae, and other possible EUV sources<sup>92-94</sup>. Enough radiation below 912 Å will seriously affect the He I/H I ratio in the ISM and observations of the interstellar/interplanetary wind<sup>89,95</sup>.

Several theoretical or empirical determinations of the expected energy density in the UV have been attempted. For heating, ionization and dissociation of ISM atoms and molecules, the important parameter is clearly the mean intensity of the UV radiation field or the equivalent energy density  $U_\lambda$ . The results of the calculations of  $U_\lambda$  in  $\text{erg cm}^{-3} \text{Å}^{-1}$  as a function of wavelength are plotted in Fig. 2.

The computations shown in Fig. 2 are hampered by many of the uncertainties encountered when establishing the total luminosity of the galaxy because they depend on an integration of all the possible galactic sources of UV radiation. Specifically, the uncertainties reflect our incomplete knowledge of the flux and space density of hot stars, especially below 1,200 Å, and of the distribution and scattering characteristics of dust grains. The calculations are, in principle, very sensitive to the exact location in space but as long as the chosen spot is well removed from the vicinity of very hot stars and associations, this effect is not very important in practice<sup>96</sup>.

Only three direct observations of the interstellar radiation density exist: Henry *et al.*'s rocket observation<sup>17</sup>, the ASTP results<sup>26</sup>, and the TD-1 sky survey<sup>97</sup> indicated in Fig. 2. The measurements are compatible with Witt and Johnson's, Henry's and an extrapolation of Jura's results but are higher than the Gondhalekar and Wilson, Grewing and Dunham estimates. Grewing's curve can be made compatible with the observations if  $n_e \approx 0.2-0.4 \text{ cm}^{-3}$ , a value much higher than the canonical value of  $0.03 \text{ cm}^{-3}$  from pulsar dispersion measures, but not to be excluded *a priori*.

## Conclusions

The scatter of the data and of the theoretical expectations in Figs 1 and 2 are due, probably in roughly equal measure, to the natural variation of the physical parameters and to observational and theoretical difficulties. This is not unexpected if the present observations are dominated by the dust scattering mechanism described above. Thus future work should explore systematically the magnitude and extent of the galactic dust source by an all-sky survey at high sensitivity (a  $3\sigma$  detection of  $\approx 100 \text{ photons cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{Å}^{-1}$ ) and moderate angular ( $0.1-0.5^\circ$ ) and spectral resolution ( $10-100 \text{ Å}$ ). A direct comparison with optical and far IR deep surveys as described by Sandage<sup>40</sup>, King *et al.*<sup>103</sup> and Drapatz<sup>104</sup> would be very useful in this context. Such surveys in the UV are being planned for some large ( $\approx 1\text{-m}$  diameter) space borne telescopes and by the wide field far UV camera on Spacelab I<sup>105</sup>.

The background spectrum at moderate spectral resolutions ( $\sim 10 \text{ Å}$ ) can provide valuable information on the emission mechanism. Measurement of the polarization of the radiation field would be valuable. Jura<sup>55</sup> has shown that one can expect a linear polarization of the backscattered light by dust grains up to 11% at  $b = 60^\circ$ , an amount easily detectable by a simple UV polarimeter mounted at the focus of presently available or planned UV telescopes. Such a measurement would be an important test of hypotheses on the origin of the observed diffuse UV background. However, extragalactic radiation might also be polarized due to transmission through aligned dust grains.

A better understanding of or a bigger effort at minimizing or avoiding contaminating sources of diffuse emissions is clearly required. Spacecraft orbits should be high enough to avoid most of the terrestrial molecular band emission in the UV that is at least above  $\approx 500 \text{ km}$  but not in the radiation belts where particle induced background can be severe. Zones subject to auroral precipitation should be avoided completely. A completely opaque shutter periodically occulting the outside

world and precise calibrations of overall throughput and field of view are a must for accurate absolute measurements of UV intensities. Techniques by which Ly $\alpha$  is rejected by at least a factor of  $10^6$  must be perfected for the region 1,050-1216 Å where no crystal filter or grating on its own can do the job.

As long as the field of view is small and/or the observations are made near the galactic poles, point sources can be avoided or corrected for fairly accurately at least in the 1,200-2,000 Å range especially if deep Schmidt plates of the UV targets are available. Below 1,200 Å more information on the space density and the luminosity of UV emitters is badly needed. A complete survey of the sky in the 100-1200 Å band of the spectrum down to limiting sensitivities of  $M_v \approx 15-20$  is also critical. A UV survey of this type is being planned by NASA for an Explorer mission.

Present observations summarized in Fig. 1 set very weak constraints on extragalactic sources of UV emissions. The question remains about the general validity over the sky of the observational lower limit of  $\approx 300 \text{ photons cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{Å}$  at 1,450 Å that presently pertains only to the limited region surveyed so far. We also need to establish whether the observed minimum is due to a veil of backscattering dust or to an extragalactic source observed through a rift in the galactic dust cloud. This will be a difficult point to resolve and polarization measurements and additional studies of dust to gas correlations may be required.

Additional sources of diffuse UV emissions might be envisioned. For example, recent observations from IUE<sup>106</sup> have been interpreted as evidence for the existence of a hot gaseous halo around our galaxy. This hot gas cools by emitting lines in the UV which could turn up in or influence moderate to high spectral resolution observations of the far UV background.

Clearly a better understanding of all contributions to the UV background is necessary before any information of cosmological significance can be distilled from the observations. First, integrated galaxy and QSO spectra extending to very short wavelengths are required to assess the background contributions and the output of ionizing radiation from these sources. With the Space Telescope it should become possible to subtract the bulk of the galaxy and QSO background light in specific fields in much the same way as star subtraction is now performed, leaving a residual presumably due to IGM emission. The intensity of this residual radiation together with information on the physical state of intergalactic Helium obtained from the He I 584 Å and He II 304 Å equivalents of the Gunn-Peterson test should set interesting constraints on or establish the amount of intergalactic matter present in the Universe.

We thank Drs Stuart Bowyer, Chris McKee, Michael Jura, Richard Henry, Jean Michel Deharveng, Gustavo Bruzual, and Adolf Witt for valuable discussions. This research is supported in part by NASA grant NGR 05-003-450 and a grant from the Danish Space Board.

*Note added in proof:* Very recently, various particle experiments have indicated that neutrinos may possess mass. Because large numbers of light leptons are produced in the big bang, the implications of this for cosmology are far reaching<sup>107</sup>. One possibility is that such massive neutrinos are unstable to radiative decay. An extragalactic component of the UV background could conceivably be due to the redshift-smeared emission from such a cosmological sea of decaying neutrinos<sup>108</sup>.

# Anomalous region on Mars: implications for near-surface liquid water

S. H. Zisk

NEROC Haystack Observatory, Westford, Massachusetts 01886

P. J. Mouginis-Mark

Department of Geological Sciences, Brown University, Providence, Rhode Island 02912

*An anomalous region has been identified on Mars from the 1971 and 1973 Earth-based Goldstone radar data. This region is characterized by coincident very high radar reflectivities and unusual smoothness. Very few realistic surface morphologies can generate such return-signals. Liquid water within ~50–100 cm of the surface is one possibility, an interpretation strengthened by an apparent seasonal variation in surface reflectivity for the same locality.*

ANALYSIS of radar measurements of the martian surface provides the possibility of interpreting textural/compositional differences of materials on a scale unobtainable from orbital images<sup>1–3</sup>. Estimations of the dielectric constant (from radar reflectivity) and small-scale slope statistics (see, for example, the C-factor analysis developed by Hagfors<sup>4</sup>) can be used to help characterize surface units<sup>5</sup> or to delineate areas with unusual material properties. Radar can provide additional evidence regarding the existence of near-equatorial regions of H<sub>2</sub>O outgassing ('oases') as proposed by Huguenin *et al.*<sup>6,7</sup>. Liquid water should produce an obvious effect on the radar characteristics of the surface (if the overburden is relatively transparent to the

radar energy), because of the very high dielectric constant of liquid water (~10 times that of solid rock and 20 times that of water ice).

### Data base

Earth-based radar measurements of the martian surface were carried out at the Jet Propulsion Laboratory's Goldstone Facility by Downs and others<sup>2</sup> in 1971 and 1973. The combined set of observations gave almost complete coverage between latitudes 14 and 22° S. Where possible, the measurements were reduced to obtain inherent reflectivity and smoothness (C-factor) of the surface material, as well as topography and other data not

**Fig. 1** Number density of radar sample points with given characteristics per 1° lat., 5° long. sample bins. *a*, Reflectivity > 9% and *C*-factor > 3,200 coincidentally; *b*, *C*-factor > 3,200; *c*, reflectivity > 9%. Note that although data points with high reflectivity or *C*-factor occur over a wide area of Mars, coincident high values in both parameters are found exclusively at the "oasis" areas proposed by Huguenin *et al.*<sup>6,7</sup> (Solis Lacus, at 20–30° S, 80–90° W; and Noachis–Hellas, at 15–25° S, 305–315° W).

considered here. In some cases the *C*-factor and hence the reflectivity could not be obtained, usually because of low signal strength resulting from rough and low-dielectric constant surfaces. In any case, a very low smoothness (*C*-factor) measurement would be suspect because of the limited Doppler bandwidth of the radar, usually resulting in an overestimate of the smoothness and a consequent underestimate of the reflectivity.

Hence the most productive type of search seemed to be for a uniform layer of liquid or of damp soil, where both reflectivity and *C*-factor were expected to be high.

**Fig. 2** Temporal variations in radar reflectivity for an area of Solis Lacus at 15.43–15.81° S. Curves represent a running five-point average at 0.16 long. intervals. Radar data was taken during 1971 ( $L_s = 258^\circ$ ) and 1973 ( $L_s = 273^\circ$  and  $294^\circ$ ) Mars oppositions at latitudes 15.44, 15.43 and 15.81° S respectively. The 'anomalous areas' refer to parts of the ground track at  $L_s = 294^\circ$  where reflectivity is > 9% and *C*-factor > 3,200. See also Fig. 4a.

## Analysis

The data were scanned for regions with a coincident high reflectivity and smoothness. Limits of 9% reflectivity and 3,200 *C*-factor (r.m.s. slopes < 1°) were chosen somewhat arbitrarily. Variations from 9 to 11% and from 2,400 to 3,200 respectively had only a slight effect on the shape of the anomalous area and on the number of observation points. For these measurement values, the formal errors (standard deviations) were ~10% of the data value.

Figure 1a illustrates the areocentric position and number densities of these high-reflectivity, high-smoothness measurements. Only two regions on the planet share this combined radar characteristic. The most prominent is a region centred at 16° S 90° W. There is also a pair of smaller areas to the north-west of Hellas. These two regions are remarkably close to the Solis Lacus (25° S, 85° W) and Noachis–Hellas (20° S, 310° W) oases proposed by Huguenin *et al.*<sup>6,7</sup>.

**Fig. 3** The seasonal variations in radar reflectivity are compared here for three regions of Mars. The horizontal axis is reflectivity and the vertical axis is the percentage of data points having less than the indicated reflectivity. *a*, Compares the strongly anomalous Solis Lacus area with the weakly anomalous Noachis–Hellas region. *b*, Compares Solis Lacus with an area in Aeolis, which is taken to be representative of Mars as a whole and shows no anomaly. Note that all three areas display an increase in percentage reflectivity with increasing martian season, but that Solis Lacus has a much more pronounced seasonal change, in addition to its higher absolute radar reflectivity.

For comparison, Fig. 1b, c indicates the areas having only their reflectivity or *C*-factor above the defined limits. Note that areas of high reflectivity are abundant, indicating a profusion of well-compacted or rocky soils on the martian surface. Areas of high smoothness are clearly less common, although they are not only restricted to the anomalies described here.

As an argument for the reality of the anomalous areas, note that the map of Fig. 1a includes radar measurements from both the 1971 and 1973 conjunctions. Almost no anomalous data points occur elsewhere on the planet, despite the near-global coverage of the data set between 14 and 22° S. In the 300 × 300 km anomaly itself, on the other hand, there are several hundred points.

## Seasonal variability

Additional characteristics of Solis Lacus can be determined by comparing radar data derived for nearly coincident ground tracks at different times of the martian year. Note that practical limitations of Earth-based radar systems dictate that radar

observations of the sub-Earth-region must be made near opposition, and hence near local martian summer. Winter measurements would at best be extremely difficult to make using Earth-based radar.

A combination of data from the 1971 and 1973 oppositions provides one example of overlapping radar swaths: Latitudes  $15.45^\circ$  S,  $15.43^\circ$  S, and  $15.81^\circ$  S were sampled between  $80$  and  $100^\circ$  W during the seasonal range from early to middle local martian summer ( $L_s = 258^\circ$ ,  $273^\circ$  and  $294^\circ$  respectively). Note that, as  $L_s$  represents the longitude of the Sun as seen from Mars, the difference between  $L_s = 258^\circ$  and  $294^\circ$  is roughly equivalent to the shift from early June to mid-July on Earth (Northern Hemisphere). Because of the nearly identical locations of these radar profiles (the north-south extent of the radar resolution cell is  $1.3^\circ$ , giving an overlap of at least 70% between swaths), the reflectivity curves for identical surfaces should be very similar. However, Fig. 2 indicates that there is a discrepancy in the reflectivity between  $L_s = 258^\circ$  and  $273^\circ$ . The  $273^\circ$  profile indicates an increase of 1.0–1.5% in the reflectivity compared with the same longitude at  $L_s = 258^\circ$ , while the  $294^\circ$  profile shows a further enhancement of 2.5–3.5%. For large parts of the region between  $82$  and  $100^\circ$  W, there is a systematically higher reflectivity with advancing  $L_s$ , that is, with season. Such a phenomenon seems to be real, as some parts of the data (for example, between  $83$ – $84^\circ$  W and  $88$ – $92^\circ$  W for  $L_s = 258^\circ$  and  $273^\circ$ ) show no difference in reflectivity despite their respective acquisition dates in 1971 and 1973. This is strong evidence for the adequacy of the calibration of the original radar data, and

also for the lack of any temporal variation in the data from instrumental causes.

In another test for possible systematic effects, we are searching the radar data at areas other than the observed anomaly for quasi-seasonal variability. Some of the results are depicted in Fig. 3. Figure 3a shows a plot of the range of variability of the reflectivity with  $L_s$  for Noachis–Hellas, which contains the only cluster of anomalous points outside the Solis Lacus region. Figure 3b shows Aeolis as an example of a non-anomalous region. Figure 3 demonstrates the 'seasonal' variability in much of the observed area, in the same sense (increased reflectivity with advancing summer), but Solis Lacus exhibits the greatest range by more than a factor of 2 of those areas so far examined. The general variability may indicate scattered expressions of near-surface water and/or permafrost, or possibly a low-level, systematic and time-dependent flaw in the calibration.

## Discussion

Measurements showing a high radar reflectivity (high dielectric constant) would be expected not only for water surfaces, but also for large areas of smooth rock within 1 m of the surface. In these conditions, anorthositic rock, with a dielectric constant  $K$  of  $\sim 5$ , would have a reflectivity of about 15% (basalt, with  $K = 9$ , is  $> 25\%$ ; water, with  $K = 81$ , is  $> 65\%$ ) if it covered the entire surface area of the radar cell ( $\sim 750 \text{ km}^2$ ). Figure 4 presents Viking Orbiter images of the same area as Fig. 2. Although few craters larger than  $\sim 10 \text{ km}$  diameter are within the radar

**Fig. 4** Viking Orbiter Images of the anomalous radar areas. *a*, Ground track shown in Fig. 2. *b*, High resolution for an area in Solis Lacus at  $18.7^\circ$  S,  $91.4^\circ$  W;  $C$ -factor, 3,186;  $L_s = 250$ ; reflection, 10.77%. Note that the images do not support a hypothetical smooth, mantle-free surface as an explanation of the radar anomaly. Numerous 10-km craters and lava flow fronts are in evidence. (USGS photomosaics I-1183 and I-1190; and Viking frame 773A10.) Scale bar, 3 km.

ground track, many moderately well preserved lava flow fronts can be easily identified. Morphologically comparable lava flows elsewhere on Mars either have radar reflectivities of 2–6% or *C*-factors <2,000 (refs 5, 8, 9). Unless the small-scale surface texture of the Solis Lacus region is unrelated to its large-scale appearance in Fig. 3, the hypothesis of an extensive rock pediment is untenable as an explanation for the high values of radar reflectivity and *C*-factor.

Moreover, to explain a seasonal variability in the reflectivity of a solid rock surface, one must hypothesize, for example, an absorptive overburden which is regularly scoured away as the summer progresses. The thickness of overburden required for the observed changes in dielectric constant have been calculated on the basis of published dielectric constants and absorption lengths for basaltic rock and loosely-compacted rock powder<sup>10</sup>. Although resonant effects of thin highly-planar soil and rock layers might be observed in laboratory conditions, such conditions do not exist on a planetary surface. Consequently, the reflectivity was calculated for a random-thickness soil layer masking a solid rock surface. Assuming dielectric constants of 2.0 for soil and 8.0 for rock, the net reflection coefficient for bare rock is 23%; for a soil layer at least 14 cm (one wavelength) thick, is 11.1%; and drops to 6% for a soil depth of 1.4 m. For lunar rock chemistry rather than terrestrial rock chemistry, the 6% reflectivity would require >10 m of rock-free soil. The problem is complicated by other factors such as variation in soil porosity with depth, but the conclusion, nevertheless, is that for rock and soil surface to exhibit a measured reflectivity of more than 11%, the soil thickness must be in the range 10–20 cm over the entire area; and that an additional deposit of the order of 1 m of soil would be required to reduce further the dielectric constant to 8%. Although there is undoubtedly a seasonal redistribution of martian dust, photographs at the Viking Lander sites<sup>11</sup> do not show the buildup of the tens of centimetres of dust that would be needed to effect a change from 11 to 8% in

the average radar reflectivity. Alternative explanations, such as seasonal changes in the bulk chemistry of the near-surface rocks, also seem to be unlikely.

Conversely, a transition from frozen water (reflectivity >7%) to liquid water (reflectivity >64%) would produce just such a striking difference in the observed radar reflectivity. Surface temperatures in the range 230–250 K have been observed, for example, at the Viking Lander sites<sup>12</sup>. While this is well below the freezing temperature for pure water, salt solutions may well exist, and have been shown<sup>13</sup> to be stable at temperatures as low as 210 K.

We conclude, therefore, that only surface materials containing liquid water are consistent with: (1) the coincident very high radar reflectivities and *C*-factor values; (2) the photographically observed surface morphology; and (3) the increase in reflectivity values from spring to summer. Some inferences can also be made about the regional extent of the near-surface expression of the liquid water at Solis Lacus. An extensive liquid water surface would have a much higher reflectivity than the observed maximum value of ~16%. More likely is a reduction in the reflectivity by an overlying layer of soil, as outlined above for the rock-soil combination, or, alternatively (or additionally), the liquid water might be observable only through random patches of the surface because of variations in the thickness or density of the overburden. In the latter case, the observed reflection values would be from a mixture of high and low reflectivity surface elements. In this case, the *C*-factor measurements would depend mainly on the highly reflecting regions (the oases) rather than the dry intervening areas. In either case, we are convinced by the radar data that liquid water does indeed exist near the surface of Solis Lacus during southern hemisphere summer.

We thank George Downs for the radar data discussed here, and Richard Simpson and Gordon Pettengill for helpful comments. This work was funded in part under NASA grant NSG 7197.

# Highly structured water network in crystals of a deoxydinucleoside–drug complex

Stephen Neidle

Department of Biophysics, University of London King's College, London WC2B 5RL, UK

Helen M. Berman & H. S. Shieh

Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

*X-ray diffraction analysis of crystals of the intercalative complex between the deoxyribonucleoside phosphate d(CpG) and the mutagen proflavine shows a highly structured arrangement of water molecules linked together by networks of hydrogen bonds to form four edge-linked pentagons per asymmetric unit. These pentagons have a general role in maximizing hydrogen bonding at 3.4-Å intervals. The conformation of the deoxyribose sugar ring at the 3' end of one strand can depend on its local aqueous environment.*

THE role of water in stabilizing and mediating the structure and conformation of nucleic acids has long been the subject of study and speculation (see, for example, refs 1–3). The conformational transitions of DNA are dependent on the level of humidity; it has been established<sup>4–6</sup> that in A-DNA each nucleotide is associated with about 8–10 water molecules whereas B-DNA has a rather greater number. As the primary hydration shell of a nucleotide can maximally accommodate fewer water molecules

than even this lower limit, it has been suggested<sup>2,7,8</sup> that 'bulk' water molecules are involved in addition to those actually hydrogen-bonded to the bases and backbone.

Features of the environment involving these latter water molecules have been investigated in several ways; the crystal structures of both ribodinucleoside phosphates GpC<sup>9</sup> and ApU<sup>10</sup> have all potential nucleobase hydrogen-bond donors and acceptors utilizing their maximum possible water interactions;

this finding has been used to investigate sequence-specific nucleic acid recognition<sup>11</sup> using water molecules as a probe of a variable group. The hydration of base pairs has been examined by quantum-mechanical methods<sup>12</sup>. Recently the solvent-accessible surfaces of tRNA<sup>8,13</sup> as well as of double-stranded DNA and RNA have been investigated, the overall important conclusion being that conformationally different forms of double-helical polynucleotides exhibit differing degrees of exposure to the proings of clustered water molecules.

It remains true that there are no simple descriptions for the water structures in oligonucleotides<sup>14,15</sup> which can be extrapolated to generalized descriptions for the hydration of nucleic acids.

We report here on the details of the arrangements of water molecules in crystals of the deoxydinucleoside phosphate d(CpG) intercalative complex with the mutagenic agent proflavine<sup>16</sup>. This structure reveals hitherto unsuspected highly ordered and structured networks of water molecules. These arrangements may provide insight into the structure of aqueous environments around nucleic acids in general, and also demonstrate the importance of water molecules in maintaining oligonucleotide and nucleic acid structure.

### Crystallographic details

X-ray diffraction data were collected on two different crystals of the d(CpG):proflavine complex. Table 1 details some data for these crystals. The superior quality of crystal 2, coupled with more observed data compared with crystal 1, enabled the structure to be successfully and fully refined by standard full-matrix least-squares techniques. Aspects of the refinement and the conformational features of this structure have already been

discussed elsewhere<sup>16</sup>. Crystal 1 proved less amenable to conventional techniques of refinement, which initially resulted in unacceptable and abnormal bond distances and angles. Successful refinement of the structure obtained from data on crystal 1 was contingent on (1) a careful procedure of constrained restrained refinement, and (2) the realization that the 3' deoxy-ribose sugar in one strand (of clear C3'-endo conformation in crystal 2) was disordered between ~50% populations of C2'-endo and C3'-endo conformers. We shall show that this disorder phenomenon is related to the water environment. Except where otherwise stated, the following descriptions are of the crystal 2 structure.

To determine the water structure, difference Fourier maps were calculated. A peak was considered to be a water molecule only if it formed reasonable hydrogen-bonding contacts with the duplex or with another water molecule candidate. The positions and temperature factors were refined; a peak was accepted to be a water molecule if there was convergence and the temperature factors remained below  $B = 30 \text{ \AA}^2$ . After the refinement, detailed analysis of distances and angles involving water molecules revealed the networks to be described. Thus, no bias towards any particular arrangement was introduced during structure solution and refinement. Water-contact distances in the structure average 2.8  $\text{\AA}$ , with a few deviating from this norm (Table 2). The maximum distance found was 3.2  $\text{\AA}$ , which, although near the limit of an acceptable hydrogen-bonding distance, did fulfill the other requirements for hydrogen-bonding geometry. The average mean-square amplitude of vibration for the first-shell water molecules is 0.18  $\text{\AA}^2$ , and for the bulk waters is 0.26  $\text{\AA}^2$ ; these relatively high degrees of thermal motion and the large estimated standard deviations of the positional parameters necessarily lead to some ambiguities in geometry which cannot be resolved by X-ray data alone. Unfortunately, the small crystal size does not make neutron analysis possible at this time.

### Overall view of the crystal structure

The asymmetric unit of the crystal contains a 2:2 complex of d(CpG) and proflavine. These pack as infinite columns of symmetry-related stacked molecules. Figure 1 shows that these columns have a stacking sequence of base pair, proflavine, base pair, proflavine, base pair, and so on. The ring nitrogen atoms and the exocyclic amino groups of the proflavine cations face the major groove. The duplex columns are grouped such that diad-

$D_{ij}$ , distance between atoms i and j.

**Fig. 1** *a*, Packing of the intercalated duplexes as viewed along the *c* axis. *m*, The major groove cavities; minor groove cavities are shaded. *b*, Water contents of the major and minor groove cavities, also viewed along the *c* axis. The minor groove polygon atoms are shaded; *D* indicates the positions of the intercalated duplexes (shown in *a*).

related pairs, which have their minor grooves facing one another, form minor groove cavities. These alternate with pairs which have their major grooves facing one another forming major groove cavities (Fig. 2). The minor-groove dimers are held together by two hydrogen bonds, and are related to the symmetry-related major groove ones by two (other) hydrogen bonds (see Fig. 2 for details). The minor groove gaps are relatively small and are filled by two-dimensional disk-like assemblies of water molecules, in contrast to the water-filled major groove cavities which are large in two dimensions and extend in infinite channels along the third (Figs 1*b*, 2).

**Fig. 2** A schematic illustration of the crystal structure viewed along the *c* axis. R, ribose; P, phosphate; C1, cytidine in strand 1; C2, cytidine in strand 2; G1, guanine in strand 1; G2, guanine in strand 2. Shaded areas indicate the base pairs on top. The dashed lines represent hydrogen bonds. The major and minor groove cavities are shown filled with water.

## Structure of the water assemblies

One might suppose that the water molecules in the major groove channels would be disordered, especially as seven of the eight waters per asymmetric unit that do not directly coordinate to the duplexes are located in these channels. However, this is not so. As Fig. 3 shows, the water molecules are linked together in a regular framework, forming edge-linked hydrogen-bonded pentagons. There are four such pentagons per asymmetric unit, each set being joined to the next via water molecule W8. A fifth pentagon is formed by two water molecules (2 and 8) which branch off two pentagons and bridge to a phosphate oxygen of a dinucleoside strand. The major groove channels are thus filled with two diad-related chains of water pentagons, with each chain coordinated to four dinucleoside strands as shown in Fig. 4. The pentagons are constructed to maximize the number of hydrogen-bonding contacts at 3.4-Å intervals along the *c* direction. The water molecules hydrogen bond with the nucleobase atoms in the major groove, as well as with the ring nitrogen atoms and the exocyclic amino groups of the proflavine cations. These hydrogen bonds are all of the 'in-plane variety'<sup>17</sup>; that is, the water molecules are in the same plane as the bases and drugs. The arrangement of the pentagons resembles that of the crystal structure of piperazine hexahydrate<sup>18</sup>, which has a 'partial pentagonal dodecahedral motif'<sup>19</sup> and is a close relative of the clathrate hydrates<sup>19</sup>.

The water arrangements in the small minor groove cavities are precisely one water molecule thick; in each one we see a planar hydrogen-bonded polygon disk of water molecules which in turn hydrogen bond to the atoms in the minor grooves of the bases. Figure 4 shows how, in contrast to the major groove structure, these interactions are 'out of plane'.

Note that in this structure, as in r(CpG)-proflavine<sup>20</sup>, some of the ribose oxygen atoms are hydrated (O1'C1 and O1'G2). Thus, this type of hydration may in fact be the rule rather than the exception as had been believed previously. Another feature of this structure is that not all the possible shell-water coordination has been observed; for example, N4C2 only forms one hydrogen bond and is not hydrated. A similar feature occurs in r(CpG)-proflavine but not in the uncomplexed dinucleoside phosphates<sup>9,10</sup>. It is not yet clear whether incomplete hydration of bases is characteristic of drug-nucleic acid complexes.

Fig. 3 The water structure alone viewed along the *b* axis. The pentagon network and polygon disk are labelled.

### Relationship between water structure and molecular conformation

Comparison of the structures of the more highly hydrated crystal 1 with the less hydrated crystal 2 shows that environmental factors may affect the conformation of a particularly flexible part of a molecule. Crystal 2 is the more highly ordered of the two, both with respect to the conformation of the molecule and the structure of the water network. In this crystal, strand 1 has C3'-endo(3', 5')C3'-endo deoxyribose conformations. Water 7 bridges O3'G1 and a phosphate oxygen, possibly stabilizing the

C3'-endo conformation at the 3' end. Strand 2 has C3'-endo(3'5')C2'-endo deoxyribose conformation (the 'mixed sugar pucker'<sup>21</sup>). In crystal 1, strand 2 has the same conformation as in crystal 2. However, on strand 1 the 3' deoxyribose sugar is disordered, albeit in a specific manner. The significant populations of this disorder are C3'-endo and C2'-endo (each ~50%). In crystal 1, water 7 is not hydrogen-bonded to either of the two disordered O3' hydroxyl positions.

These findings on sugar pucker elucidate further the contentious issue of the role ascribed to sugar conformations in intercalated dinucleosides. Our earlier analysis of a ribo(CpG)-proflavine complex structure<sup>20</sup> showed C3'-endo ribose pucker at both ends of the two dinucleoside strands. Even though this structure, by its very existence, showed that intercalation did not necessarily require (or produce) 'mixed sugar' pucker, it has been suggested that proflavine is a special intercalator<sup>21</sup>, presumably on account of the hydrogen bonding of a proflavine cation to the exterior of a duplex via the 3' sugar. Our observation<sup>22</sup> that dinucleoside intercalation is concomitant with an increase in the glycosidic torsion angle at the 3' end to a relatively high value suggested that C2'-endo sugar pucker at this end might be slightly favoured in view of the correlation between C2'-endo pucker and high  $\chi$  values. This deoxy(CpG)-proflavine complex, on the other hand, clearly shows no major preference for either pucker at the 3' end. We conclude that this pucker is unimportant and plays no real part in defining the intercalation geometry. The precise nature of the pucker is dependent on the environment around the sugar and may be considered as an end effect. We would expect the situation in solution to parallel that found in these crystals, with states flipping between the major C2'/C3'-endo puckers to be present.

### Discussion

Such highly structured water has never been observed in crystal structures of nucleic acids, their constituents or other biological molecules although circular networks of hydrogen bonds (involving hydroxyl as well as water atoms) have been reported in the structure of  $\alpha$  cyclodextrin<sup>23</sup>. Although the structures of the nucleic acid fragments, GpC and ApU, are highly hydrated, the waters are evenly distributed in a first hydration shell.

Fig. 4 The hydrogen bonding of the water molecules to the four dinucleoside phosphate strands. The five pentagons are labelled and shaded. The numbering of each water molecule is shown. The view is similar to Fig. 3. Waters 3 and 20 of pentagon I form a square-planar hydrogen-bonding arrangement with N7G and O6G of strand 1, and water 14 hydrogen bonds to N4 of that same strand. Waters 6 and 24, which branch off pentagon IV, form a similar pattern with N7G and O6G of strand 2 of the diad-related duplex. Water 13 of pentagon I hydrogen bonds to N10 of the intercalated proflavine, and water 11, which branches off pentagon IV, hydrogen bonds to N10 of the stacked proflavine. The exocyclic amino groups N15 and N16 of the diad-related stacked proflavine molecules hydrogen bond to waters 18 and 8 respectively.

Two questions arise: (1) Why does this orderly framework appear in this crystal? and (2) is the pentagon network of any wider significance? Although neither question is fully answerable some observations may be made.

The characteristics of the water framework are partially due to the crystal packing. This structure exhibits very few duplex-duplex interactions (Fig. 2), possibly because it contains deoxyribose sugars. It therefore lacks the hydrogen bonding of the O2' hydroxyl which in the most extreme example helped mediate the proflavine-duplex cross-linking observed in proflavine-CpG. Instead, the crystal contains two water-filled cavities. Probably the water disks in the minor groove cavities merely accommodate themselves to the relatively small space allowed by the hydrogen-bonded dimers. The major groove cavities are considerably more hydrophilic with two positively charged nitrogen atoms facing one another. As there are no anions such as  $\text{SO}_4^{2-}$  mediating these charges, the cavity is necessarily quite large. Solvent-solvent interactions, therefore, become as important as solvent-solute interactions in maintaining the crystal order. In this structure the solvent-solvent interactions take the form of a pentagon network of waters, which can be

likened to a trellis to which the major groove heteroatoms hydrogen bond.

Presumably the pentagon network is not the only plausible arrangement of water molecules—a network of hydrogen-bonded hexagons can also be envisaged. However, aside from the frequent observation of pentagonal water networks in clathrate crystals<sup>19</sup>, the geometry observed is such that it clearly forms an optimum number of attachments to drug and dinucleoside atoms. Indeed, the pentagon geometry is well suited to link 3.4-Å-separated heterocycles. Furthermore, the evident propensity of the pentagons to readily associate together and the inherent flexibility of the individual pentagon strongly suggest that nucleic acids of size greater than the dinucleoside level could readily accommodate related pentagonal clusters.

We thank Drs S. H. Kim and J. L. Finney for discussions of this manuscript. ## Amplification of rearranged repeated DNA sequences in cereal plants

J. R. Bedbrook\*, M. O'Dell & R. B. Flavell

Cytogenetics Department, Plant Breeding Institute, Trumpington, Cambridge CB2 2LQ, UK

*A simple repeating unit of the rye genome, previously known in tandem arrays, has now been shown to occur also in more complex repeating units. One such unit has been cloned and found to contain some sequences unrelated to the simple repeat. It is proposed that tandem arrays of complex repeats are often produced by amplification of DNA segments formed by recombination of different repeats and possibly unique sequences. Some complex variants of repeats are not in high copy number on all rye chromosomes.*

REPEATED sequences constitute much of the chromosomal DNA of higher eukaryotes. Many higher plant species have more than 70% of their DNA in the form of repeated sequences<sup>1</sup>. Consequently, studies of the formation and organization of families of repeated sequences may contribute substantially to our understanding of plant chromosome structure. Formation of families of repeated sequences must occur often during evolution to account for the differing spectra of repeated DNA sequences in the chromosomes of closely related species<sup>2</sup>. Repeated sequences are frequently reamplified during evolution<sup>2</sup>. This was concluded from comparative studies on repeated sequences common to the genomes of the related gramineae species—wheat, rye, barley and oats<sup>2</sup>. About 20% of the rye genome consists of short, species-specific, repeated sequences interspersed with short repeated sequences also found in wheat and other related cereals<sup>3,4</sup>. These results suggested that the repeated sequences which are reamplified are often in new combinations which must have been generated by

sequence rearrangement. Studies of the structure of specific repeated sequences of rye heterochromatin have also suggested sequence rearrangement before amplification because each has a simple sub-repeat interspersed with an unrelated non-subrepeating unit<sup>5</sup>. If closely related sequences are amplified in different combinations then different repeating units should have sub-repeats in common.

To investigate this prediction we have probed the wheat and rye genomes with a simple 120-base pair repeating unit that is predominantly organized in tandem arrays<sup>5</sup> to search for more complex units which are likely to have been created by recombination of the 120-base pair sequence with other sequences before amplification. We describe here the identification, structure and chromosome distribution of such complex forms of this repeat. One of the many complex reamplified forms has been purified by cloning in a bacterial plasmid. Its repeating unit is 2.2 kilobases long and consists of a few of the simple repeat units interspersed with unrelated sequences. The 2.2-kilobase repeat is present on all seven rye chromosomes but other repeats containing sequences related to those in the 2.2-kilobase repeat seem to be present only on some rye chromosomes.

\* Present address: CSIRO Division of Plant Industry, Canberra, ACT Australia.

**Fig. 1** Hybridization of a cloned repeated sequence to rye DNA digested with various restriction endonucleases. Rye DNA (15 µg) prepared from purified nuclei<sup>5</sup> was digested to completion *a*, with *Hae*III (A), *Bam*HI (B), *Bgl*II (C), *Hind*III (D), *Eco*RI (E) and *b*, with *Eco*RI (F), *Eco*RI + *Bam*HI (G) and *Bam*HI (H), and fractionated by agarose gel electrophoresis. The agarose concentration in the gel was 1.5%. Electrophoresis conditions were as described previously<sup>5</sup>. Electrophoresis was from top to bottom of the panel. The DNA was transferred from the gel to a sheet of nitrocellulose filter as described by Southern<sup>19</sup>. The filter was hybridized using a <sup>32</sup>P-labelled cRNA probe prepared *in vitro* by *E. coli* RNA polymerase using a cloned example of a 120-base pair highly repeated DNA sequence as the template (see text for details of repeat). 5 × 10<sup>5</sup> c.p.m. were used in the hybridization. Hybridization was in 2 × SSC containing 100 µg tRNA at 62 °C for 18 h. (SSC is 0.15 M sodium chloride + 0.015 M sodium citrate). Unhybridized probe was removed from the filters by extensive washing with 1 × SSC at 60 °C. Stable hybridization was revealed by autoradiography. The major 2.2-kilobase repeats in the *Eco*RI digests are arrowed.

### Complex forms of a simple tandem repeat

The family of rye repeats we have analysed for more complex reamplified forms comprises ~2% of the genome<sup>5</sup>. It consists principally of 120-base pair repeating units arranged in tandem arrays. This was determined by digesting rye DNA with *Hae*III restriction endonuclease, fractionating the resulting fragments by agarose gel electrophoresis, transferring the fragments to a nitrocellulose filter and hybridizing them with <sup>32</sup>P-labelled cRNA prepared from a cloned 120-base pair repeat. (The cloning of this repeat unit in the bacterial plasmid pBR322 is described elsewhere<sup>5</sup>.) *Hae*III digestion (Fig. 1, track A) revealed a progression of fragments at intervals of 120 base pairs. This pattern would be expected from a family of tandemly arranged repeats in which each unit repeat sequence contains a *Hae*III site but occasionally loses it by random mutation so that some dimers, trimers and higher multimers remain after *Hae*III digestion. Figure 1 also shows that the restriction enzymes *Bam*HI (track B), *Bgl*II (track C), *Hind*III (track D) and *Eco*RI (track E) cut sequences complementary to the 120-base pair repeat probe DNA infrequently. *Bam*HI and *Eco*RI produce an integral series of fragments with a periodicity of 120 base pairs. Such fragments presumably arise from the creation of restriction sites by mutation. *Bgl*II and *Hind*III do not generate such an integral series of fragment lengths. Therefore there is probably no sequence closely related to the *Bgl*II and *Hind*III recognition sites within the basic repeating unit. That *Bam*HI and *Eco*RI sites occur randomly in the 120-base pair family is supported by double-enzyme digestion. Digestion with both *Eco*RI and *Bam*HI (Fig. 1, track G) produces a higher proportion of the family in lower molecular weight fragments than does

digestion with either *Eco*RI (Fig. 1, track F) or *Bam*HI (Fig. 1, track H) alone.

The results in Fig. 1 (tracks B–E) also show that the clone of the 120-base pair unit hybridizes to specific restriction fragments which are in relatively much higher copy number than the integral progression of 120-base pair fragments. All hexanucleotide restriction enzymes used produce such fragments. These fragments could have arisen in the genome by (1) amplification of specific arrays of 120-base pair units, one member containing a particular hexanucleotide recognition site, or (2) the amplification of more complex pieces of DNA that include 120-base pair units. That at least some of these major variant forms contain sequences other than 120-base pair units is suggested by their being present in *Hind*III and *Bgl*II digests, even though these enzymes do not produce an integral series of 120-base pair fragments. We have shown that the major variant revealed in the *Eco*RI digests (arrowed in Fig. 1) does contain a complex piece of DNA besides 120-base pair units. This was achieved by characterizing cloned examples of the major variant.

### Major *Eco*RI variant is not a simple tandem array of 120-base pair units

The major high copy number variant in *Eco*RI digests is 2.2 kilobases long and migrated with a DNA band of strong fluorescence in *Eco*RI digests of total rye DNA (Fig. 2a). This band was recovered from an agarose gel and cloned in the vector plasmid pACYC184. The resulting clones were screened with the 120-base pair sequence by the method of Grunstein and Hogness<sup>6</sup>. Two clones that hybridized with the 120-base pair repeat sequence and co-migrated with the major band in *Eco*RI digests of *Secale cereale* DNA were obtained (Fig. 2a). A physical map of one of the cloned 2.2-kilobase rye DNA fragments is shown in Fig. 2b. The sequence contains sites for endonucleases *Pst*I and *Sal*I. The 120-base pair repeat unit hybridizes only to the 1,200-base pair *Sal*I-*Eco*RI fragment and the 1,400 base pair *Pst*I-*Eco*RI fragment and not to the 1,000-base pair *Sal*I-*Eco*RI fragment or the 800-base pair *Pst*I-*Eco*RI fragment (results not shown). The 120-base pair repeat unit hybridizes to only three *Hae*III fragments of 220, 200 and 120 base pairs which map within the 1,200-base pair *Sal*I-*Eco*RI fragment. Thus it was deduced that the 120-base pair repeat unit in the high copy *Eco*RI variant is interspersed with unrelated sequences, all the sequences together forming a unit repeat defined by *Eco*RI, *Pst*I or *Sal*I. For ease of discussion we shall refer to the DNA unrelated to the 120-base pair unit as 'spacer' DNA. The 2.2-kilobase repeat units are clustered in rye chromosomes because dimer and trimer forms can be seen in partial *Eco*RI digests of rye DNA. Fig. 2c illustrates the deduced arrangement of the 2.2-kilobase repeat in the genome.

### The 2.2-kilobase repeat unit family may have been formed later than the 120-base pair repeat unit family

Two lines of evidence suggest that the 2.2-kilobase repeat unit family may have been formed in the rye genome more recently than the 120-base pair repeat unit family. First, in complete digests of rye DNA >80% of the 2.2-kilobase repeat DNA is in the monomer form after digestion with *Eco*RI, whereas <40% of the 120-base pair repeat DNA is in the monomer form after complete digestion with *Hae*III (Fig. 1). Assuming that dimer, trimer and such forms result from the random loss of restriction sites with time, and that each base has an equal probability of being altered, then more of the six-base pair *Eco*RI sites would be expected to have been lost than four-base pair *Hae*III sites if the families were of equal age. Second, the 2.2-kilobase repeat family is not highly repeated in wheat (see below; Fig. 5) whereas the 120-base pair family is<sup>5</sup>. This suggests that the 120-base pair family was amplified before wheat and rye diverged from their common ancestor<sup>2</sup>, and the 2.2-kilobase repeat family was amplified after the rye and wheat ancestors diverged,

**Fig. 2** The structure of a cloned example of a complex form of the 120-base pair repeat. Rye DNA (100 µg) was digested to completion with *EcoRI* and fractionated on a 1.5% low melting point agarose (LMP Seakem) gel. The major repeat band in this digest (see a, lane A) was excised and heated at 65 °C together with 2 vol (w/v) 50 mM Tris-HCl, pH 8.0, 0.5 mM EDTA for 3 min. The solution was cooled to 37 °C and an equal volume of water-saturated phenol (at 37 °C) was added. The mixture was homogenized, allowed to equilibrate to room temperature and the phases separated by centrifugation at room temperature. The phenol phase was removed and the aqueous phase re-extracted with phenol. The final aqueous phase was precipitated with 2.5 vol ethanol. The precipitated DNA was washed twice with 70% ethanol, dried and dissolved in 20 µl H<sub>2</sub>O. The DNA was ligated to 0.1 µg *EcoRI*-linearized pAC184 DNA<sup>5</sup>. The ligated DNA was used to transform the *E. coli* strain HB101. Transformants were selected on media containing tetracycline at 5 µg ml<sup>-1</sup>. Transforming plasmids containing inserted fragments were screened by testing for chloramphenicol sensitivity. These transformants were then screened for sequences complementary to the 120-base pair repeat using the assay described by Grunstein and Hogness<sup>6</sup>. Plasmid DNA from such transformants was prepared<sup>20</sup>, digested with *EcoRI* and fractionated by agarose gel electrophoresis together with rye DNA. a, Track A shows rye DNA, tracks B and C show two plasmids. b, A physical map of one such plasmid. The double thickness line shows the region complementary to the 120-base pair repeat. This was determined by hybridizing cRNA prepared from a cloned example of the 120-base pair repeat to the plasmid illustrated in 2a (track B), digested with *EcoRI* + *SalI*, *EcoRI* + *PstI*, and *EcoRI* + *HaeIII*, fractionated by gel electrophoresis and transferred to nitrocellulose paper. We have assumed that the three *HaeIII* fragments (see text) which hybridize to the clone of the 120-base pair repeat are adjacent. The region has been positioned as illustrated because the 200-base pair fragment carries the *EcoRI* site. c, The deduced structure of the complex cloned repeat (the 2.2-kilobase repeat, see text) in the genome. The double thickness line represents that portion of the repeat assumed to include sequences complementary to the 120-base pair repeat. bp, Base pairs.

although we cannot rule out the possibility that the 2.2-kilobase repeat has been deleted from wheat.

### Origin of the 2.2-kilobase repeat family

To investigate the arrangement of the spacer DNA sequences in *Secale* genomes, a probe prepared from DNA fragments within the 2.2-kilobase spacer DNA (the 800-base pair *EcoRI*-*PstI* fragment) was hybridized to size-fractionated *Secale cereale* (rye) and *Secale silvestre* DNAs digested with *EcoRI* and *HindIII* endonucleases. Figure 3 (tracks E-H) shows that the spacer DNA hybridizes to many repeated sequence DNA bands in DNAs digested with *EcoRI* or *HindIII*. The pattern of hybridization produced when the 120-base pair repeat DNA was used as probe is shown as a control (Fig. 3 A-D). The spacer DNA probe hybridized to DNA fragments containing from >20

kilobases to >0.5 kilobases. This hybridization pattern suggests that sequences related to those in the 2.2-kilobase spacer DNA exist in many diverse arrangements in the genome. This diversity and the origin of the 2.2-kilobase repeat can be explained by proposing that short pieces of DNA frequently undergo re-arrangement by recombination during genome evolution to form many permutations of linear order. Specific permutations of these sequences are then amplified to create repeat families, such as the 2.2-kilobase repeat family, definable by their unique length and linear permutation of rearranged sequences.

The 2.2-kilobase repeat contains two components that we have distinguished—the 120-base pair sequences and what we have called 'spacer sequences'. Two pieces of evidence suggest that these subcomponents have existed as repeats in cereal genomes for long evolutionary time periods. First, much of the 2.2-kilobase spacer DNA is present in rye, wheat and barley genomes because most (but not all) of the 800-base pair *EcoRI*-*PstI* fragment of the 2.2-kilobase repeat (see Fig. 2b) renatures with repeated sequence kinetics when sheared and renatured with a large excess of sheared wheat and barley DNAs<sup>7</sup>. This suggests that these sequences were first amplified before wheat, rye and barley diverged<sup>2</sup>. The presence of the 120-base pair sequence in wheat is shown in Fig. 5 and has also been demonstrated by *in situ* hybridization to wheat chromosomes<sup>5</sup>. Second, sequences in the rye genome related to the subcomponents of the 2.2-kilobase repeat are very heterogeneous. This was determined by forming hybrid duplexes *in vitro* between rye DNA fragments and a cloned example of 120-base pair repeats or the 800-base pair *EcoRI*-*PstI* fragment from the 2.2-kilobase repeat. The thermal stabilities of these duplexes were

**Fig. 3** Organization of spacer DNA from the 2.2-kilobase repeat in *Secale* species DNA. The 800-base pair *EcoRI*-*PstI* fragment (see Fig. 2b) was prepared from preparative *EcoRI* + *PstI* double digests of the cloned 2.2-kilobase repeat fractionated on agarose gels as described in Fig. 2 legend. <sup>32</sup>P-labelled cRNA prepared from this fragment was hybridized to *S. cereale* (rye) DNA digested with *EcoRI* (E) or *HindIII* (G) and *S. silvestre* DNA digested with *EcoRI* (F) and *HindIII* (H). As a control, <sup>32</sup>P-labelled cRNA prepared from the 120-base pair repeat was hybridized to *S. cereale* digested with *EcoRI* (A) or *HindIII* (C) and to *S. silvestre* DNA digested with *EcoRI* (B) or *HindIII* (D). The DNA was fractionated by electrophoresis on 1.0% agarose gels (from top to bottom) and transferred to nitrocellulose filters before hybridization. Hybridization and washing conditions were as in Fig. 1 legend. Hybridization was assayed by autoradiography. The major 2.2-kilobase repeats are arrowed.

**Fig. 4** Thermal stability of duplexes formed *in vitro* between rye DNA and the 120-base pair or 2.2-kilobase spacer DNA. DNA from a clone of the 120-base pair repeat or the 800-base pair *EcoRI-PstI* fragment from 2.2-kilobase spacer, radiolabelled with  $^{32}\text{P}$  by nick translation ( $10^5$  c.p.m. of specific activity,  $10^8$  c.p.m.  $\mu\text{g}^{-1}$ ) and was mixed with 200  $\mu\text{g}$  rye DNA sheared to 300–400 nucleotide lengths. After denaturation the DNA was incubated to  $C_0t$  0.3 in 0.12 M phosphate buffer at 60°C. The renatured DNA was adsorbed on to hydroxyapatite at 60°C in 0.12 M phosphate buffer, then melted off by raising the temperature in defined steps. Denaturation of total rye repeated DNA was determined by measuring the elution of  $A_{260}$ . Denaturation of the labelled DNA duplexes was determined by precipitating the eluted DNA with 5% TCA in the cold, collecting it on GF/B filters and scintillation counting. Sheared native rye DNA was similarly eluted as a control.  $\circ$ , 2.2-kilobase spacer duplexes;  $\blacktriangledown$ , 120-base pair DNA duplexes;  $\nabla$ , total renatured repeated rye DNA;  $\bullet$ , native rye DNA. Results plotted are means from two experiments.

determined by binding them to hydroxyapatite and melting them off by raising the temperature in defined steps. Both sets of duplexes show a very broad melting curve with a  $\Delta T_m$  of  $\sim 11^\circ\text{C}$  with respect to native DNA (Fig. 4). A broad melting curve is expected of hybrids with a large range of mispaired bases. These melting curves therefore indicate considerable heterogeneity amongst sequences related to the 120-base pair and spacer DNA. Assuming that repeated sequence divergence is related to the age of the repeated sequence family, sequences related to the 120-base pair and to spacer DNA have existed as repeats for a long and similar time period. The sequence heterogeneity of

these families contrasts with the relative homogeneity of a family described elsewhere which is specific to *S. cereale* and absent from *S. silvestre* and which was amplified presumably relatively recently<sup>5</sup>.

The hybridization experiments of Fig. 3 provide evidence that both subcomponents of the 2.2-kilobase repeat have been involved in rearrangements. Probes prepared from both the 120-base pair sequence and the spacer sequence hybridize to a smear of DNA fragments ranging in size from  $>20$  to 0.5 kilobases suggesting that sequences complementary to these DNAs are interfaced with many different sequences in the chromosomes. Figure 3 also shows that many permutations of the ancestral sequences are reamplified. The two subcomponents of the 2.2-kilobase repeat hybridize to many bands other than the integral size progression of the 120-base pair tandem repeat. Furthermore, several of the bands (other than the 2.2-kilobase repeat itself) which hybridize to the two subcomponents of the 2.2-kilobase repeat have the same length. This suggests that sequences related to the 120-base pair and spacer DNA sequences have been amplified together to form repeat families differing from the 2.2-kilobase repeat family. DNA sequences homologous with 2.2-kilobase spacer DNA have been involved in amplification (and possibly rearrangement) events since the separation of *S. cereale* and *S. silvestre* because repeated DNA bands visible in hybridizations to *S. cereale* (Fig. 3, tracks E and G) are absent from the hybridizations to *S. silvestre* (Fig. 3, tracks F and H) and vice versa.

The heterogeneity of the sequences in the genome related to the subcomponents of the 2.2-kilobase family makes it unlikely that these sequences have been rearranged or translocated to new sites in the genome as 'intact, mobile' elements such as a bacterial insertion sequence<sup>8</sup> or the copia, 412 or 279 elements in *Drosophila*<sup>9</sup>. If spacer DNA always inserted itself intact, all the *HindIII* restriction fragments from the genome which hybridize to spacer DNA would be expected to be larger than the spacer itself because spacer DNA in the 2.2-kilobase repeat does not contain a *HindIII* recognition sequence. The results in Fig. 3 (tracks G and H) show three repeat families in *S. cereale* and two in *S. silvestre* which hybridize to 2.2-kilobase spacer DNA but which are shorter than the calculated size of the 2.2-kilobase repeat spacer. Thus spacer DNA must at least undergo deletion or be the target of insertion itself by a DNA sequence containing a *HindIII* recognition sequence.

**Fig. 5** The presence of complex forms of the 120-base pair repeat in individual chromosomes of rye. DNAs from rye (variety King II), *S. silvestre* and *Triticum aestivum* (variety Holdfast) and the complete set of alien addition lines of the *S. cereale* variety King II in the *T. aestivum* variety Holdfast were digested with *EcoRI* (a) and *BamHI* (b) and fractionated by electrophoresis on 1.5% agarose gels. The fractionated DNA was transferred to nitrocellulose filters and hybridized with  $^{32}\text{P}$ -labelled cRNA prepared using a cloned example of the 120-base pair repeat. Hybridization was assayed by autoradiography. Track A, rye DNA; track B, *S. silvestre* DNA; track C, *S. cereale* chromosome 5R in a *T. aestivum* background DNA; track D, chromosome 6R; track E, chromosome 2R; track F, chromosome 4R; track G, chromosome 1R; track H, chromosome 3R; track I, chromosome 7R; track J, *T. aestivum* DNA. The major 2.2-kilobase repeats revealed by *EcoRI* digestion are indicated by the arrow at the extreme left. The other arrows mark bands which vary in different addition line tracks.

## Chromosomal distribution of reamplified variants of the 120-base pair repeat

Wheat-rye addition lines have enabled us to investigate quantitative variation of specific reamplified variants of the 120-base pair repeat between the chromosomes of the rye variety King II. Each wheat-rye addition line has a full complement of wheat chromosomes and a single pair of rye chromosomes<sup>10</sup>. DNA isolated from each of the addition lines, from King II rye, from *S. silvestre* and from wheat (variety Holdfast) were digested with *Eco*RI (Fig. 5a) or *Bam*HI (Fig. 5b) restriction endonucleases, fractionated by gel electrophoresis, transferred to nitrocellulose paper and hybridized with a probe prepared from the 120-base pair repeat. The results in Fig. 5 show that *S. cereale* (rye) (track A) and *S. silvestre* (track B) have essentially the same set of amplified variants of the 120-base pair repeat. Wheat DNA (track J), however, lacks a high concentration of the major variant in the *Eco*RI digest. It is therefore possible to use the addition lines to investigate the chromosomal distribution of the rye 2.2-kilobase repeats. Figure 5a shows that the 2.2-kilobase family is present in each of the seven rye chromosomes examined as is the major family in *Bam*HI digests (Fig. 5b). However, two variants in *Eco*RI digests are present in high copy number only in chromosomes 1R, 6R and 7R (Fig. 5a, arrowed in tracks D, G and I) and one or two relatively minor variants in *Bam*HI digests (Fig. 5b, arrowed in track F) may be present in high copy number only in chromosome 4R.

That some amplified variant forms of the 120-base pair repeat may be chromosome specific or on only some chromosomes suggests that specific amplified sequences may occur initially at a specific location in the genome and are only subsequently distributed to other chromosomes by recombination.

## Discussion

High copy number variants within families of repeated sequences have been found in a few other species by methods similar to ours—in satellite DNAs of mouse<sup>11</sup>, *Drosophila*<sup>12</sup> and man<sup>13-15</sup>. Only for *Drosophila*<sup>12,16,17</sup> and man<sup>13-15</sup>, as far as we

are aware, have results been previously reported which illustrate chromosome-specific variants of repeated sequences. An intriguing question is whether chromosome-specific variation is maintained for functional reasons or merely reflects the site of reamplification before dispersal<sup>14</sup>.

The hypothesis described here to account for the origin of the complex 2.2-kilobase family of repeated sequences is relevant to the structure and evolution of a large proportion of plant chromosome DNA because complex permutations of short repeated and single-copy sequences are common in plant chromosomes<sup>18</sup>. Furthermore, in cereal species, a large fraction of the DNA consists of short repeated sequences common to many species, interspersed with repeated sequences which are species-specific or found only in very closely related species<sup>3,4</sup>. DNA with this sequence arrangement has probably evolved by sequence rearrangement and amplification like the 2.2-kilobase repeat family described here.

We thank Dr D. Lonsdale for criticisms of an earlier version of this paper.

# Cloning and sequence analysis of cDNAs encoding two distinct somatostatin precursors found in the endocrine pancreas of anglerfish

Peter Hobart, Robert Crawford, LuPing Shen, Raymond Pictet & William J. Rutter

Department of Biochemistry & Biophysics, University of California, San Francisco, California 94143

Complementary DNAs for two distinct anglerfish somatostatin peptides (termed I and II) have been cloned in bacterial plasmids and sequenced. The nucleotide sequence for somatostatin I encodes a large precursor peptide (molecular weight 13,300) in which the somatostatin hormone is at the carboxyl terminus. The predicted 14-amino acid sequence for anglerfish somatostatin I is the same as mammalian somatostatin. Somatostatin II is also synthesized as part of a larger precursor (molecular weight 14,100) with the presumptive somatostatin hormone also at the carboxyl terminus. The 14-amino acid sequence of somatostatin II differs from somatostatin I at two internal residues (Tyr in place of Phe 7 and Gly in place of Thr 10). The two different somatostatins may have distinct biological activities. Homologies in the amino acid sequences of the two peptides outside the somatostatin moiety suggest other regions of the molecules have biological functions.

SOMATOSTATIN is a 14-amino acid peptide which modulates the secretion of several peptide hormones and may also have a role in neurotransmission. Somatostatin was originally isolated from the hypothalamus as an inhibitor of pituitary growth hormone secretion<sup>1</sup>, but it has more recently been localized in

the D cells of the endocrine pancreas<sup>2,3</sup> and shown to be an inhibitor of both insulin and glucagon secretion<sup>4</sup>. In addition, it has been detected in discrete epithelial cells lining the gut<sup>5</sup> and can inhibit the secretion of several gastrointestinal hormones including secretin<sup>6</sup>, gastrin<sup>7</sup> and cholecystokinin<sup>8</sup>. However,

somatostatin is not universally involved in regulating peptide hormone secretions because it does not affect the secretion of several other hormones including follicle-stimulating hormone and luteinizing hormone<sup>9</sup>. Studies on the localization of somatostatin in neuronal tissue reveal its presence in several other regions of the brain<sup>10,11</sup> as well as the spinal cord<sup>12</sup> and the sympathetic nerve fibres<sup>13</sup>. Injection of somatostatin into the cranium results in loss of motor activity, suggesting that it is a potent depressant of certain parts of the central nervous system<sup>14</sup>. These properties have led to the postulate that somatostatin is a neurotransmitter. That a single hormone exhibits this spectrum of biological activities is a regulatory paradox.

These observations have engendered considerable interest in the regulation of somatostatin synthesis and secretion by the various dispersed somatostatin-producing cells. In common with several other peptide hormones, somatostatin is synthesized as part of a larger precursor peptide that is subsequently processed<sup>15,16</sup>. Peptides up to 10 times the size of somatostatin have been found which react with somatostatin antibodies<sup>17,18</sup> and there is evidence that this larger peptide is also able to inhibit growth hormone secretion by the pituitary<sup>19</sup>. Furthermore, a 28-residue peptide containing somatostatin has recently been isolated from porcine intestinal tissue<sup>20</sup>.

A direct approach to characterizing the complete somatostatin precursor, as well as the somatostatin mRNA and gene, involves construction of bacterial plasmids containing the somatostatin mRNA sequence, using nucleic acid technology. This approach is facilitated by the availability of a tissue which is highly enriched in somatostatin mRNA. In most vertebrates, there is no tissue with a sufficiently high proportion of somatostatin-producing cells to undertake such experiments. However, in some fish, and in particular the anglerfish (*Lophius americanus*), the endocrine pancreas (termed Brockmann body) is easily separated from exocrine tissue and, furthermore, in comparison with mammals, is highly enriched in D (somatostatin-producing) relative to B (insulin-producing) cell types<sup>21</sup>. Therefore, we have used the anglerfish Brockmann body as a source of somatostatin mRNA.

We present here the results of cloning in bacteria and subsequent sequence analysis of a cDNA molecule which predicts the complete preprosomatostatin peptide sequence (somatostatin I) synthesized by the fish endocrine pancreas. In addition, we present the sequence of another cDNA molecule, also present in the fish endocrine pancreas, encoding a second preprosomatostatin precursor (somatostatin II) which differs by two amino acids in the 14-residue hormone sequence. The finding that two distinct precursor peptides are synthesized in the fish pancreas leads us to suggest that more than one gene may be involved in the hormonal activities now attributed to somatostatin.

## Synthesis and cloning of fish cDNA

Poly(A)<sup>+</sup> mRNA from Brockmann body tissue was isolated as described in Fig. 1 legend. This fraction contains two major classes of mRNA: 700 ± 25 and 840 ± 25 bases. This is consistent with a previous report that *in vitro* translation of the mRNA from anglerfish Brockmann bodies results in only a few predominant protein products<sup>22</sup>. Double-stranded cDNA was synthesized from poly(A)<sup>+</sup> mRNA, tailed with deoxycytidine residues and cloned in the *Pst*I site of the plasmid pBR322 which had been previously tailed with deoxyguanosine (described in Fig. 1 legend). Approximately 3,000 tetracycline-resistant transformants were obtained from 75 ng of tailed cDNA.

To screen the transformants, the most frequent cDNA inserts were selected by hybridization to a single-stranded cDNA probe synthesized from Brockmann body poly(A)<sup>+</sup> RNA. A few plasmids containing large inserts were prepared from the cDNA-positive colonies. Purified inserts from these plasmids were labelled by 'nick translation' and tested for their ability to cross-hybridize with each other. The most frequent cDNA insert among the colonies selected by this method has been subsequently sequenced and found to be fish preproinsulin<sup>23</sup>.

**Fig. 1** RNA was extracted from anglerfish Brockmann bodies (Biological Associates) by the guanidine thiocyanate method<sup>23</sup>. One gramme of Brockmann body tissue yields approximately 6.5 mg of total RNA. Polyadenylated RNA was purified using oligo(dT)-cellulose affinity chromatography. 1.35 µg of single-stranded cDNA was made from 10 µg polyadenylated RNA using AMV reverse transcriptase (J. Beard, lot no. 1577) in the following reaction mix; 40 mM Tris-HCl, pH 8.3, 10 mM MgCl<sub>2</sub>, 56 mM β-mercaptoethanol, 0.5 mM dATP, dGTP, dTTP, 0.15 mM <sup>3</sup>H-dCTP (specific activity 5.2 mCi µmol<sup>-1</sup>), 25 µg ml<sup>-1</sup> oligo(dT) (P-L Biochemicals), 40 µg ml<sup>-1</sup> poly(A)<sup>+</sup> RNA, 15 units reverse transcriptase per µg RNA. Incubation was at 42 °C for 30 min and then at 68 °C for 2 min. The reaction was stopped by the addition of NaEDTA (pH 8.0) to 20 mM, chromatographed over Sephadex G-75 and precipitated with ethanol. RNA was removed by alkali treatment (0.2 M NaOH, 23 min at 68 °C) and the second strand cDNA synthesis was carried out in the following reaction mixture using DNA polymerase I; 100 mM Na HEPES pH 6.9, 75 mM KCl, 10 mM MgCl<sub>2</sub>, 10 mM dithiothreitol (DTT), 100 mM dNTPs, 0.8 µg ml<sup>-1</sup> single-stranded cDNA (boiled for 3 min just before addition), and 75 units per µg *Escherichia coli* DNA polymerase I (Biolabs). Incubation was at 14 °C for 2 h. The reaction volume was made 20 mM NaEDTA, extracted once with phenol/chloroform/isoamyl alcohol (50:48:2) and passed over a Sephadex G-75 column. In preparation for dC tailing, the hairpin loops of the double-stranded DNA (ds-cDNA) were clipped and made blunt ended using S<sub>1</sub> micrococcal nuclease (Miles) in a 30-min reaction at 37 °C (175 units per µg ds-cDNA). After organic extraction and Sephadex G-75 chromatography to remove small DNA fragments, 300 ng of trimmed double-stranded (ds)-cDNA was tailed using calf thymus terminal transferase in a 30-min reaction at 37 °C containing 140 mM K cacodylate, 30 mM Tris base (pH 7.8), 1 mM CoCl<sub>2</sub>, 0.1 mM DTT, 25 µM dCTP ([α-<sup>32</sup>P]dCTP, 8.36 µCi nmol<sup>-1</sup>), and 150 units terminal transferase per µg ds-cDNA<sup>24</sup>. Preliminary experiments indicated approximately 30 bases are added to the 3' end in these conditions. The dC-tailed ds-cDNA was then annealed to an equimolar amount of dG-tailed pBR322 at a concentration of 1 µg ml<sup>-1</sup> using sequential 2 h incubations at 42, 30 and 14 °C (ref. 35). The hybrid plasmid DNA was precipitated with ethanol and used to transform *E. coli* λ1776 in P2/HV2 containment conditions in compliance with NIH Recombinant DNA Guidelines<sup>36</sup> and selected for tetracycline resistance. To screen with various labelled probes, recombinant colonies were grown on Whatman 541 cellulose paper, lysed *in situ* and prepared for hybridization according to the Grunstein and Hogness procedure<sup>37</sup>. The filters were hybridized to a <sup>32</sup>P-labelled cDNA probe synthesized from anglerfish Brockmann body RNA and plasmid DNA was isolated from those colonies giving a strong autoradiographic signal using a cleared lysate procedure<sup>38</sup>. Two plasmids (pLaS1 and pLaS2) were selected on the basis of their size and their cDNA inserts purified on preparative acrylamide gel electrophoresis. Purified insert cDNA from these plasmids was labelled by 'nick translation'<sup>39</sup> and hybridized to anglerfish poly(A)<sup>+</sup> RNA which had been previously chromatographed on a 2% agarose methyl mercury gel<sup>40</sup> and transferred to diazotized cellulose paper<sup>24</sup>. Hybridization was for 48 h at 42 °C. Hybridized filters were autoradiographed after washing three times (100 ml volume, 10 min each) in 0.3 M NaCl, 0.03 M Na citrate, 0.1% (w/v) SDS at 20 °C and then in the same manner using 15 mM NaCl, 1.5 mM Na citrate, 0.1% SDS at 50 °C. Lane 1, *Hind*III-digested λ DNA and *Hae*III-digested ΦX174 DNA MW standards. Lane 2, ethidium bromide staining of anglerfish Brockmann body (1 µg poly(A)<sup>+</sup>-enriched RNA); lane 3, hybridization of transferred anglerfish poly(A)<sup>+</sup> RNA to pLaS1 <sup>32</sup>P insert DNA; lane 4, hybridization of transferred anglerfish poly(A)<sup>+</sup> RNA to pLaS2 <sup>32</sup>P insert

**Fig. 2** Sequencing strategy for pLaS1 and pLaS2 cDNA inserts. Both cDNAs are oriented 5' to 3' according to the mRNA sequence and are numbered so that the first base coding for the hormone somatostatin I or somatostatin II is no. 1, and with all bases in the 5' direction given negative numbers. Thickened areas of the line for each cDNA indicate the predicted translated region of the mRNA sequence and the double thickness at the 3' end of the translated sequence indicates the region coding for the hormone. Not included are the poly(dG)-poly(dC) tails at the ends of the cDNA inserts which were between 12 and 25 base pairs long. Below each sequence are arrowed lines indicating the restriction sites used for kinasing the DNA and the direction and extent of DNA sequence determined using that labelled fragment. To prepare purified fragments for each labelling or sequencing reaction, DNA fragments were cut by the indicated restriction endonuclease, separated by polyacrylamide slab gel electrophoresis and electroeluted. All acrylamide gel electrophoreses were carried out in 100 mM Tris-borate pH 8.1, 2.5 mM NaEDTA using 5–7% polyacrylamide (20:1, acrylamide/bisacrylamide). To end-label, the DNA fragments were treated for 30 min at 65 °C with 8–20 units of bacterial alkaline phosphatase (Worthington) in 0.1 M Tris-HCl pH 7.4, 0.1 M NaCl, phenol extracted (2×), and then treated with 4–8 units of T4 polynucleotide kinase (BioLabs) at 37 °C for 30 min in a reaction mixture containing 50 mM Tris pH 7.6, 10 mM MgCl<sub>2</sub>, 5 mM DTT, 200  $\mu$ Ci (3,000–4,000 Ci mmol<sup>-1</sup>) [ $\gamma$ -<sup>32</sup>P]ATP. The 5' end-labelled DNA fragment was subsequently cut by an intervening restriction endonuclease, separated by gel electrophoresis, eluted, concentrated and ethanol precipitated as described above. Sequence reactions were carried out according to Maxam and Gilbert<sup>41</sup>.

Two additional non-cross-hybridizing non-insulin cDNA inserts (later termed pLaS1 and pLaS2) were selected. The size of the mRNAs specific to both pLaS1 and pLaS2 were determined by 'Northern' gel transfer<sup>24</sup> analysis to be approximately 700 bases (see Fig. 1, lanes 3, 4). By a similar analysis, the other major poly(A)<sup>+</sup> mRNA of 840 bases corresponds to preproinsulin (data not shown). The two non-insulin cDNA inserts were sequenced according to the strategy presented in Fig. 2. The nucleotide sequence of pLaS1 (563 base pairs) predicts the entire peptide sequence of preprosomatostatin I whereas pLaS2 (594 base pairs) predicts the sequence of preprosomatostatin II. The 14-amino acid sequence of the hormone in fish preprosomatostatin I is identical to mammalian somatostatin. This corroborates an earlier sequence analysis of fish somatostatin<sup>25</sup>.

As expected from the lack of cross-hybridization and its restriction map (Fig. 2), the nucleotide sequence of pLaS1 insert DNA differs substantially from that of pLaS2; nevertheless, the molecules are clearly related. As shown in Fig. 3, the nucleic acid sequences were aligned based on the recognized homologies present in the regions coding for the hormone and the signal peptides. Additional homologies in the translated and in the untranslated regions were revealed by computer analysis. A molecule of approximately 45% overall homology can be constructed by the insertion of gaps in the nucleotide sequence. Beginning with the first AUG codon at the 5' end of the sense strand, translation of pLaS1 predicts the sequence of a 121-amino acid peptide which contains the somatostatin hormone at its carboxyl terminus (Fig. 3). This leaves 37 bases of untranslated sequence at the 5' end of the cDNA and 158 bases 3' to the stop codon and before the poly(A) tail. If translation is initiated at the first AUG codon (amino acid position -107), the predicted preprosomatostatin I peptide has a molecular weight of 13,328. This is approximately the size of somatostatin precursors which have been detected in both mammalian and fish tissue<sup>17,18,42</sup>. The region of the peptide following this AUG comprises a sequence of hydrophobic amino acids characteristic of the signal peptide described for other precursors of secretory proteins<sup>26</sup>. The sequence Leu-Leu-Val-Leu-Leu in position

-96 to -92 of this region is found in the signal peptide of fish preproinsulin and is located at approximately the same distance from the initiating methionine in both precursor molecules<sup>22,23</sup>.

Translation from the first AUG codon in pLaS2 predicts a 125-amino acid peptide (MW 14,100) which also contains a characteristic signal peptide at its amino terminus and a 14-residue somatostatin-like peptide at its carboxyl terminus. This somatostatin II peptide differs from somatostatin I by two internal amino acids at position 7 (Tyr instead of Phe) and position 10 (Gly instead of Thr). The hormone sequences are flanked at their amino terminus by the residues Arg-Lys. Such contiguous basic residues are frequent sites for post-translational processing of hormone precursors<sup>27,28</sup> and suggest that both somatostatins are cleaved from their precursors by a trypsin-like enzyme activity. There is additional homology extending to amino acid -18. This region of the anglerfish precursors is in turn homologous with a 28-amino acid somatostatin-containing peptide isolated from porcine gut<sup>20</sup> (see Fig. 4). The anglerfish somatostatins have arginine residues at position -15 and thus can both be cleaved by a trypsin-like activity to give similar 28-amino acid peptides. These conserved features of the molecules suggest that this 28-amino acid sequence may have biological activity. The additional 2-amino acid homology evident in the two fish precursors may indicate a recognition sequence for a processing enzyme. This same Leu-Glu-Arg sequence is found at a second position (-66/-64) in preprosomatostatin II.

Apart from the characteristic hydrophobic amino acid composition, there is little homology in the signal peptide region of the two preprosomatostatins.

The untranslated regions of pLaS1 and pLaS2 have some areas of sequence homology when aligned as shown in Fig. 3. However, it is not clear that these common sequences have a functional role. The homologies (>55%) in the cloned portion of the 5'-untranslated region are largely due to the repeated sequence XCAGAX. In the 3'-untranslated region, as in many other eukaryotic mRNA sequences, pLaS1 has a AAUAAA sequence beginning 20 bases from the polyadenylation site<sup>28-31</sup>. This same sequence is present in pLaS2 but at a position 40

**Fig. 3** The mRNA nucleotide sequence and single-frame translation of pLaS1 and pLaS2. For comparative purposes, the two nucleic acid sequences are aligned (by the use of gaps) to show regions with a significant amount of base homology. The translated amino acid sequences are numbered by designating the first residue (Ala) of the somatostatin I and somatostatin II peptides as no. 1. The amino acids towards the amino terminus of the precursors are numbered negatively and those towards the carboxy terminus of the hormones are numbered positively. The asterisks indicate homologous bases along the pLaS1 and pLaS2 nucleotide sequence. We have, in addition, sequenced two other cDNA fragments which cross-hybridized with pLaS1 and two which cross-hybridized with pLaS2. In all three cases the sequences were identical to those presented here, eliminating the possibility of any significant errors resulting from the reactions involved in cDNA synthesis.

bases from the poly(A) site whereas a slightly different sequence, AAUUA AAA, is found at the corresponding position closer to the 3' end of the mRNA.

## Characteristics of somatostatin I and II precursors

Our results show that, in common with many other hormones, somatostatin is synthesized as part of a larger precursor peptide. This precursor contains a signal peptide which may be released during the transit into the endoplasmic reticulum; the resultant prosomatostatin would be approximately 97 residues for somatostatin I and 101 residues for somatostatin II (with MWs 10,600 and 11,600 respectively). The function of this form of the precursor, which is more than five times the size of somatostatin, is interesting. It may be cleaved in one step to yield somatostatin alone and thus have no function other than to act as a connecting peptide between the somatostatin hormone and the signal peptide. Alternatively, prosomatostatin, or a smaller, intermediate-sized precursor containing the somatostatin sequence, may be biologically active because 'big somatostatin' exhibits somatostatin activity<sup>19</sup>. Finally, there may be a related or separate biologically active peptide encoded in the precursor in analogy with the adrenocorticotropin (ACTH) precursor<sup>28</sup>. However, a computer analysis of both preprosomatostatin I and II detected no distinct homologies with any known protein sequence (search completed by the National Biomedical Research Foundation, Georgetown University).

## Two somatostatin activities?

The finding of two distinct mRNAs which generate different somatostatin molecules raises questions concerning possible functions of multiple somatostatins and the nature of somatostatin hormone activity measured in animal tissues by immunological procedures. The somatostatin I and II hormones are sufficiently closely related structurally for it to be likely that they cross-react to some degree in biological activity and/or radioimmunoassays. However, it is unclear whether they exhibit the same range of biological activities. Previous studies using chemically synthesized somatostatin analogues have shown selective inhibition of secretion of insulin or glucagon by the pancreas and/or growth hormone by the pituitary<sup>32</sup>. These studies indicate significant functional differences in somatostatin receptors of the different target cells. Therefore, it is possible that there are several somatostatins with common immunological determinants but with selective activities on different target cells. A test of the biological activity of somatostatin II as well as prosomatostatins I and II may help to resolve these questions.

## LETTERS

### Observations of optical flares in the recurrent X-ray transient A0538–66

G. K. Skinner

Department of Space Research, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK

The recurrent transient X-ray source A0538–66 probably lies at the distance of the Large Magellanic Cloud (LMC) and is consequently among the most luminous stellar sources known ( $L_x \sim 8 \times 10^{38} \text{ erg s}^{-1}$ , 2–17 keV) (refs 1–4). It has a unique combination of properties. The X-ray outbursts which have been observed were separated by multiples of a 16.6-day period. Some were relatively long, for example the  $n=3$  and  $n=4$  events (using the nomenclature of Johnston *et al.*<sup>2</sup>) lasted ~14 days and ~1 day respectively, but others lasted only a few hours. Observation of the  $n=3$ , 4, 11 outbursts<sup>3</sup> recently led to an improved error box and the proposal of a  $B \sim 15$  optical counterpart<sup>4</sup> (star 'Q' in Fig. 1 of ref. 4) shown on archival plates to be variable. The star was found to have an absorption spectrum characteristic of a  $B$  star. I report here an examination of 85 plates taken with the UK Schmidt telescope at Siding Spring, between 1974 and 1979 including some taken at the time of the X-ray observations. Dramatic flares observed on three of the plates, separated by intervals of 16 days and synchronized with the X-ray outbursts, confirm the proposed identification.

The region of sky containing A0538–66 has been included in numerous plates taken with the UK Schmidt telescope, both in its survey role and as part of non-survey programmes. The plates have been taken in various colours but in particular a series of 35  $B$  plates overlapping the Ariel 5 and HEAO 1 X-ray observations have been measured with an iris photometer. The plates were taken largely on nights when conditions were not sufficiently good for survey work and are of rather variable quality. The plate-to-plate consistency obtained for a series of

comparison stars was 0.15 mag r.m.s. Excluding two plates, the r.m.s. scatter of the observations of the proposed candidate, star 'Q', about their mean was only slightly greater (0.20 mag) and this difference may be attributable to the influence of a  $B \sim 17$  star 4 arc s away which is resolvable from Q on some, but not all, plates and which complicates the photometry. On each of the two remaining  $B$  plates Q was brighter by  $\Delta B = 1.8$ . Of these two plates one was taken during the 1-day long  $n=4$  X-ray outburst (17.1 UT on 4 September 1977) (Fig. 1a) and the other close to the time that the  $n=5$  X-ray outburst was expected (at 18.4 UT on 20 September 1977)<sup>3</sup>. Scans through the region made by the Large Area Sky Survey (LASS) instrument on HEAO 1 1.7 h before the latter optical observation and 4.7 h after it did not detect any X-ray activity (Fig. 1b).

The candidate star lies within the boundary of the stellar association NGC2034 and the surrounding region of the plates contains several stars of similar magnitude with which visual comparisons are easily made. This enabled a simple search to be made for optical flares on 50 further original plates and copies. The plates were of various colours but at least three of each type were compared (3U, 3B, 7V, 3R, 12I, 11J, 4H $\alpha$ , 7 non-standard). In most cases photographic enlargements of the region were used in the comparison. Changes of 0.5–1 mag would have been detectable, depending on the plate quality and colour. The flares of  $\Delta B = 1.8$  are immediately apparent in this way.

The search led to the discovery of a third flare, on a plate taken using 098 emulsion and only a polaroid filter and therefore sensitive to a wide range of wavelengths from ~4,000 to 7,000 Å. The plate was taken during the  $n=6$  X-ray outburst, at 17.1 UT on 7 October 1977 (Fig. 1c). No detailed measurements have been made as the original plate is still in Australia, but comparison with copies of other plates taken with the same filter/emulsion combination suggests that the increase above the quiescent level is about the same as the 1.8 mag increase during the flares seen on  $B$  plates.

On eight plates taken between those on which the flares are seen the star was apparently in its normal state. These include two plates taken 23 and 24 h before that showing the third flare.

As there is no certainty that the optical luminosity was the same at the time of the 7 October plate as it was for the two *B* plates showing flares, there is no firm information on the colour in the flare state. The similarity of the three events suggests that the colour may not be very different from that in the quiescent state. Colour measurements based on the measurements of UK Schmidt plates are given in Table 1. Compared with the results of Johnston *et al.*<sup>4</sup> these figures suggest the star is brighter (by 0.8 mag) and suggest a UV excess not apparent from their spectrum. Their results are based on plates taken in 1941–45, when the mean level may have been different, and on a spectrum obtained with the Anglo-Australian Telescope in July 1979, when the zenith distance was large, perhaps making the figures unreliable at shorter wavelengths (M. J. Ward, personal com-

**Table 1** Photometry of the counterpart of A0538–66

|                 | <i>B</i> | <i>U</i> – <i>B</i> | <i>B</i> – <i>V</i> | <i>V</i> – <i>R</i> | Broad band |
|-----------------|----------|---------------------|---------------------|---------------------|------------|
| Quiescent state | 15.0     | –1.5                | 0.1                 | 0.6                 |            |
| During flares   | 13.2     |                     |                     |                     |            |
| Difference      | 1.8      |                     |                     |                     | ~1.8       |

UVR measurements are from plates taken on the same night (10–11 h UT on 19 March 1979) presumably in the quiescent state. Colours are calculated assuming the mean *B* magnitude from 33 plates taken between November 1976 and January 1978 (not including those showing flares). Standards from refs 6–8 were used for calibration but none is close to star Q both in brightness and position and in addition to the effects of the internal scatter discussed in the text each measurement is subject to a calibration uncertainty of the order of 0.25 mag. Thus errors in colours could be as large as 0.4 mag.

munication). In addition the calibration uncertainties are large, as indicated in Table 1.

To estimate the optical luminosity we assume that the flares had the same spectrum as a *B*2.5 main sequence star, consistent with the quiescent-state spectrum discussed above. Then, assuming a distance modulus of 18.6 corresponding to the LMC and allowing for an extinction of 0.2, the *B* = 13.2 flare state corresponds to  $M_{\text{bol}} = -7.6$  or an optical luminosity of  $3 \times 10^{38} \text{ erg s}^{-1}$ . This is ~3 times higher than the X-ray flux measured at very nearly the same time as the *n* = 3 optical observation. If the spectrum is not that of a *B* star but is similar to the emission spectrum expected from an accretion disk<sup>5</sup> then the optical luminosity would be higher still. Thermal bremsstrahlung from an optically thin plasma at 6.6 keV (ref. 1) capable of producing the observed X-ray flux would produce a *B* band flux ~250 times below that observed.

The star was observed by Johnston *et al.* in what can now be recognized as its flare state (although not as bright as those reported here) on a plate taken on 12 November 1945. Combining this with all other optical and X-ray observations (except the anomalously long and late *n* = 3, 4 events) and assuming a constant period plus a random phase jitter, best fits are obtained for periods of  $16.668 \pm 0.002$  or  $16.645 \pm 0.002$  days depending on whether the 1945 event is attributed to *n* = –693 or *n* = –594. The r.m.s. deviation is 1.5 h in either case. Other periods differing by steps of 0.023 days from these are possible but imply a jitter at least twice as large.

The three UK Schmidt telescope plates showing flares were among 26 obtained between September 1977 and March 1978 which have been examined. They occurred on consecutive cycles of the 16.6-day period. The fact that none of the 59 plates from other times during the period 1974–79 which have been examined shows any sign of flares suggests that the source may not always be active, although the X-ray activity lasted at least from June to December 1977 and there was previous optical activity in 1945. Plates taken near the times when outbursts would have been predicted on the basis of each of the above possible periods are among the 59 from other years which have been examined without detecting further activity. However, because of the uncertainty in the duration of the flares and of the existence of phase jitter, this evidence is inconclusive. The observation of the optical flare at *n* = 5 shows that either the X-ray outburst was very short or an optical flare occurred without a corresponding X-ray outburst.

Measurements of the plates to determine the position of the centroid of the emission in the flare state place it within 0.1 arc s of that in the quiescent state, effectively excluding the possibility of another, normally invisible star being the source of the events. Thus these results place beyond doubt the association of star Q with A0538–66, as proposed by Johnston *et al.*<sup>4</sup>

The discovery of the flaring optical counterpart considerably improves the chances of establishing whether there is a true constant period, perhaps a binary orbital period, controlling the activity of the system or whether a roughly constant characteristic time between outbursts produces a pseudo-periodic

**Fig. 1** The times of the three observations of optical flares (dotted lines) compared with the HEAO 1 LASS X-ray data. Plate exposures and X-ray measurement times are short compared with the ordinate scale (10–20 min; 5 s). The graphs are aligned and labelled according to the ephemeris given in ref. 4. In each case the ordinate shows X-ray intensities in units of the intensity of the Crab Nebula. The *n* = 4 X-ray event (a) is one of two anomalously long and late ones; the *n* = 6 event (c) is more typical. The points plotted in b are all  $2\sigma$  upper limits. Not all available upper limits are shown but there were no observations during the gap around the time of the optical observation as the satellite was being used in pointed mode.

behaviour. The surprising absence of emission lines in the spectrum of the counterpart suggests that away from outburst the star is comparatively normal and the prospects of spectroscopic studies helping to unravel the nature of this unique system are consequently also good.

Regarding A0538-66 as an X-ray transient, its X-ray spectrum and the properties of the optical counterpart suggest that it should be classed with systems such as A0535+26, 4U0115+63 and A1118-61, which tend to have hard spectra and high mass counterparts, rather than the soft, low mass transients such as A0620-00, A1524-617 and 1H1705-250. Optical flares coincident with X-ray outbursts are common in the latter class (see review in ref. 9), but in these cases the optical flux is only a minor contribution to the overall luminosity during outburst. For example, although during the X-ray transient outburst of A0620-00 the optical counterpart increased in brightness by 3 mag, the optical luminosity was still less than the X-ray luminosity by a factor of 85. Much of the increase in optical flux in such cases is probably due to reprocessing of X rays in the atmosphere of a star whose quiescent state luminosity is low or in an accretion disk.

Similarly, optical bursts have been detected in coincidence with X-ray bursts from MXB1735-44 (refs 10, 11) and 4U1837+04 (ref. 12) but again the X-ray luminosity greatly exceeds the optical luminosity (by factors of  $5 \times 10^4$  and  $3 \times 10^5$  respectively) and the optical flux can be attributed to reprocessing.

Optical luminosities comparable with, or in excess of, the X-ray luminosity are known to occur in bright, high mass systems. Optical variability has been reported in several cases, but the changes have shown no correlation with X-ray outbursts. Nor have they been as large as those described here. Even if the distance of A0538-66 is regarded as uncertain, the relative increase in optical flux compared with the X-ray flux is unique. If the source is indeed at the distance of the LMC, then the absolute value of the increase is even more remarkable.

Many existing plates must contain records of the behaviour of A0538-66 and I would be pleased to liaise between astronomers having such material. A position and finding chart are given in ref. 4.

I thank P. Murdin for pointing out the existence of the plate material and for valuable discussions, S. Shulman for assistance with HEAO 1 data and the following for making plates and copies available: R. Davies, J. Meaburn, W. Garner and C. Butler. I particularly thank Miss M. Sims and other members of the UK Schmidt Telescope Unit both at Edinburgh and Siding Spring for their help.

**Note added in proof:** Since completing the above work I have identified a further flare on a blue plate from the Harvard plate stack. The plate was taken at Bloemfontein, South Africa, on 8-9 October 1932. The plate quality does not permit good measurements to be made but the increase seems to be similar to that on the UK Schmidt plate events. A plate taken 24 h earlier shows possible signs of some brightening but on others from the same year star Q seems to be similar to the 1974-79 quiescent state. Measurements of other plates from the collection confirm that the star was generally  $\sim 0.5$  mag less bright in 1941-46. The 1932 event is consistent with a period of 16.667 days if a rather large jitter is assumed, but excludes the possibility of a 16.645-day period.

## Neutrinos and the age of the Universe

E. M. D. Symballsty, J. Yang & D. N. Schramm

Astronomy and Astrophysics Center, Enrico Fermi Institute, The University of Chicago, 5640 South Ellis Ave, Chicago, Illinois 60637

The age of the Universe should be calculable by independent methods with similar results. Previous calculations<sup>1,2</sup> using nucleochronometers, globular clusters and dynamical measurements coupled with Friedmann models and nucleosynthesis constraints have given different values of the age. We report here a consistent age,  $T_U$ , whose implications for the constituent mass density are very interesting and are affected by the existence of a third neutrino flavour,  $\tau$ , and by allowing the possibility that neutrinos may have a non-zero rest mass.

Nucleocosmochronology places a lower limit on  $T_U$  of  $\geq 8.7$  Gyr essentially model independently<sup>3</sup> as this value represents the mean age of the  $r$ -process elements. A model dependent  $T_U$  can be determined from a chemical evolution model of the Galaxy. The major uncertainty entailed is relating the mean age of the elements to the duration of nucleosynthesis. Such an analysis leads to a model dependent upper limit<sup>4</sup> on  $T_U$  of  $\sim 20$  Gyr. However, there are non-standard galactic evolution models which cannot be eliminated and which give ages greater than this.

Big-bang nucleosynthesis began with Gamow<sup>5</sup> who recognized that an early hot universe would allow nuclear reactions to occur to build heavier elements. With the microwave radiation confirming the hot early universe it is obvious that the primordial abundances of the light elements— $^2\text{H}$ ,  $^3\text{He}$ ,  $^4\text{He}$  and  $^7\text{Li}$ —become useful probes<sup>6</sup>. For example, the observed primordial  $^4\text{He}$ ,  $Y$ , leads to constraints on the number of light ( $M_e \leq 1\text{ MeV}$ ) neutrino types<sup>7,8</sup>. Detailed big-bang nucleosynthesis calculations relates  $Y$  to the present baryon density,  $\rho_B$ , which is at the very least a lower limit to the universe density,  $\rho$ . The exact relationship between  $Y$  and  $\rho_B$  is weakly dependent on the neutron half life and we have used  $\tau_n$  of 10.61 min (ref. 9). The deuterium density decreases with increasing baryon density thereby setting a  $\rho_B$  upper bound from D/H lower bound. In addition,  $Y$  increases with increasing  $\rho_B$ , and the observational limit,  $Y \leq 0.25$  and the fact that at least three neutrino flavours exist also sets an upper limit<sup>7,8</sup> on  $\rho_B$ . The fact that both D and  $Y$  measurements argue against large  $\rho_B$  coupled with the fact that these arguments are rather insensitive to baryon density fluctuations<sup>10,11</sup> further supports the big-bang model. Kazanas *et al.*<sup>2</sup> and Gott *et al.*<sup>1</sup> achieved their restrictive limits on  $T_U$  by equating the nucleosynthesis constrained  $\rho_B$  with the  $\rho$  implied by galactic dynamics. Here by allowing for non-zero mass neutrinos  $\rho > \rho_B$  is possible. The resulting age constraints are somewhat relieved but are still significant.

Globular cluster ages,  $T_{GC}$ , independently determine  $T_U$  and it has been found that  $T_{GC}$  may be written in terms of the primordial stellar helium abundance and their metal abundances,  $Z$ . The result from stellar evolution models is<sup>12</sup>:

$$\log_{10} T_{GC} \approx 0.035 + 2.085(0.3 - Y) - 0.034(\log_{10} Z + 3) \quad (1)$$

where  $10^{-3} \leq Z \leq 10^{-4}$  and  $T_{GC}$  is in 10 Gyr units. The range for  $Z$ , following Iben<sup>12</sup>, encompasses metal poor clusters ( $Z \sim 10^{-4}$ ) to clusters where turnoff ages indicating young stars are observed ( $Z \geq 10^{-3}$ ). The  $Y$  uncertainty will be discussed elsewhere. Carney<sup>13</sup> has recently calculated globular cluster ages by comparing effective temperatures of main sequence turnoff points with model isochron results and he has compared his results with the evolutionary isochrons of other workers. When these results are normalized to the proper  $Y$  and  $Z$  values they are in good agreement with equation (1). We assume a negligible time interval between the big bang and cluster formation.

**Fig. 1** The age of the Universe,  $T_U$  plotted against the primordial helium abundance,  $Y$ . The vertical line representing  $Y = 0.25$  corresponds to the  $Y$  upper limit. The globular cluster ages are bracketed by their metal abundance,  $10^{-4} \leq Z \leq 10^{-3}$ . The constant density line,  $\Omega = 0.04$ , represents a lower limit to the total Universe density and  $H_0 = 40$  ( $\text{km s}^{-1} \text{Mpc}^{-1}$ ) represents the lower limit on the Hubble constant. The maximum allowed Hubble constant is found to be  $68$  ( $\text{km s}^{-1} \text{Mpc}^{-1}$ ).

The third independent calculation of  $T_U$  involves a Friedmann model using zero cosmological constant ( $\Lambda = 0$ ) representing a homogeneous isotropic universe presently matter dominated with negligible pressure. One can write:

$$T_U = F(\Omega)H_0^{-1} \quad (2)$$

where  $H_0$  is the Hubble constant and  $F(\Omega)$  is a monotonically decreasing function of  $\Omega$ , where  $\Omega = \rho/\rho_c = 8\pi\rho GH_0^{-2}/3$  (an exact description of  $F(\Omega)$  is given in ref. 1). The density parameter,  $\Omega$ , determines whether the Universe is open ( $\Omega \leq 1$ ) or closed ( $\Omega > 1$ ).

As pointed out by Kazanas *et al.*<sup>2</sup> precise values for the quantities necessary for  $T_U$  through the three methods—production and element abundance ratios for nucleocosmochronology,  $Y$  and  $Z$  for globular clusters, and  $H_0$  and  $\rho$  (or  $\Omega$ ) for Friedmann calculations—would enable exact independent  $T_U$  determinations which could then be compared for consistency. Unfortunately none of the sets of quantities is known precisely and hence it is more useful to explore the range of the parameters that intersect  $T_U$  domains for a consistent age. A non-zero intersection will restrict  $T_U$  whereas a null intersection suggests a model flaw and forces one to question some of our basic astrophysical theories.

The calculation is most easily shown by plotting  $T_U$  against  $Y$  (Fig. 1). We expect a firm upper limit of  $Y$  to be 0.25 and a possible lower limit of 0.20. This range follows from Yang *et al.*<sup>7,8</sup> who pointed that a  $Y$  value between 0.20 and 0.25 seems to be emerging from various experimental and theoretical determinations based on quite different input physics and assumptions. Recent measurements of population II subdwarfs indicating<sup>14</sup>  $Y \sim 0.19 \pm 0.04$  falls into this range within its uncertainty. However, it does cause concern in that the lower limit of 0.20 may be too restrictive.

From galaxy dynamics<sup>15</sup> the probable limits for the total density parameter are  $0.04 \leq \Omega \leq 0.4$  whereas the baryon lower bound is  $\Omega_B \geq 0.001$  obtained from the local stellar neighbourhood<sup>16</sup> or from the extremes of the mass implied for central regions of galaxies.

The previous calculation of Kazanas *et al.*<sup>2</sup> assumed a two neutrino standard big-bang model, that is the electron and muon neutrinos contributed to the radiation dominated early Universe density. The standard model now assumes three massless neutrinos because of the discovery of the  $\tau$  lepton<sup>17</sup>. Even though the current experimental upper limit<sup>18</sup> of the  $\nu_\tau$  mass is 250 MeV, which does not qualify as low mass for big-bang

nucleosynthesis calculations, the  $\nu_\tau$  is expected to be of low mass. Astrophysical constraints require it to be either very low mass and long lived or to have a mass  $\geq 10$  MeV and a lifetime  $\leq 10^3$  s (refs 19, 20).

Figure 1 shows  $T_U$  plotted against  $Y$  for the standard  $3\nu$  model. If  $\Omega = 0.04$  is an accurate lower limit and if it represents a baryon density then no concordant age is found. Even if 1 Gyr was allowed between the big bang and cluster formation no consistent age would be found. Thus if  $\nu_\tau$  is a low mass or massless neutrino then  $\Omega_B$  must be less than the lower limit on  $\Omega$ . This means that the bulk of the mass of the Universe would not be in the form of 'normal' baryonic matter. The most obvious alternative form is lepton matter. The recent reports of neutrino masses reported by Reines<sup>21</sup> and the scales of neutrino clustering with galaxies are consistent with this<sup>22</sup>. In fact one could argue that this discrepancy almost requires that neutrinos have mass or that some other form of nonbaryonic matter exist.

It is also interesting that the maximum allowed Hubble constant is  $68 \text{ km s}^{-1} \text{Mpc}^{-1}$ . This conclusion is independent of the neutrino/baryonic mass ratio and derives only from the upper limit on  $Y$  and the globular cluster age consistency. This is true even in a lepton dominated universe as equation (2) requires  $\Omega (\geq \Omega_B) \leq 1$  and as a result for a given  $T_U$ ,  $H_0$  may only be lower than  $H_0$  calculated for a baryon dominated universe because  $F(\Omega) \leq F(\Omega_B)$ . This  $H_0$  upper limit conflicts with claims<sup>23</sup> of  $H_0 \sim 100 \text{ km s}^{-1} \text{Mpc}^{-1}$ . If  $H_0$  were unequivocally shown to be large then the standard globular cluster age calculations and the assumption that the cosmological constant is zero would be questioned. However, the difficulties in direct measurements at  $H_0$  suggest that there is no need to question such assumptions at present. It is probable that observationally  $H_0 \geq 40 \text{ km s}^{-1} \text{Mpc}^{-1}$ . This limit crosses the globular cluster ages at  $\rho_B \sim 1.7 \times 10^{-32} \text{ g cm}^{-3}$  and  $\Omega_B \sim 0.0053$  implying that  $Y \geq 0.135$  and  $T_U \leq 24$  Gyr. The aforementioned baryon density bound,  $\Omega_B \geq 0.001$ , is not very restrictive as such a constant density line would not intersect globular cluster ages until well above 25 Gyr. Likewise, the  $\Omega < 0.4$  bound is not restrictive as  $T \leq 0.25$  already requires  $\Omega_B \leq 0.1$  (ref. 22). Likewise any  $\Omega$  upper bound greater than 0.4 which may arise from lepton density considerations would not be restrictive.

The existence of a massive neutrino allows for a large lepton contribution to the Universe density and hence a lower baryon density (and lower  $Y$ ) is possible. In fact, should neutrinos dominate the Universe density, which would be the case for a neutrino mass of a few electron volts<sup>22</sup>, then the  $T_U/Y$  relationship is broken as we have assumed  $\Omega_B$  to be the dominant fraction of  $\Omega$  in relating  $T_U$  to  $Y$ . Then, the aforementioned  $T_U \leq 24$  Gyr would be the upper limit. We recognize that nucleocosmochronology coupled with a galactic evolution model set an upper bound of 20 Gyr and is more restrictive than this but we hesitate to use the 20 Gyr bound because of the uncertainties in the galactic evolution models. Significantly the 20 Gyr limit straddles the allowed range for  $Y$  and its credibility is also strengthened by the fact that the mean age of the elements normalized by the duration of nucleosynthesis has been found to be approximately constant for several galactic models<sup>4</sup>.

If the  $\tau$  neutrino should be discovered to be massive ( $\geq 1$  MeV) then the standard big-bang model should include only two neutrinos contributing to the early Universe density. The electron and muon neutrino model allows for a consistent age of 13.8–15.8 Gyr assuming  $\Omega_B = \Omega \geq 0.04$ . This restricts  $0.237 \leq Y \leq 0.250$  and constrains the maximum Hubble constant to  $64 \text{ km s}^{-1} \text{Mpc}^{-1}$ . There would be no consistent age should  $Y < 0.237$  or  $\Omega_B > 0.18$ . If we allow for a lepton dominated universe in this case as well and extend the lower bound to  $Y > 0.13$  then one again finds  $T_U \leq 24$  Gyr.

We have shown that there is no consistent age in the standard cosmological model if the  $\tau$  neutrino has a mass  $< 1$  MeV unless the density of the universe is significantly greater than the baryon density. Such a result argues for an earlier suggestion<sup>22</sup> that neutrinos having masses of the order of tens of electron volts. Regardless of the mass of  $\nu_\tau$  and the mass of neutrinos in

general we re-emphasize that no consistent solution exists between standard globular cluster models and high values of the Hubble constant. If  $H_0$  were shown observationally to be  $\geq 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ , then either standard globular cluster calculations must be seriously in error or else there must be a cosmological constant so that  $H_0^{-1}$  is no longer an upper limit for  $T_U$ .

Allowing for  $\rho$  to be  $\gg \rho_B$  we find that the consistent age is

$$13.8 \text{ Gyr} \leq T_U \leq 24 \text{ Gyr}$$

If  $\rho_B = \rho$  then consistent solutions are only possible if  $M(\omega_\tau) > 1 \text{ MeV}$  which from ref. 18 would require  $M(\nu_\tau) > 10 \text{ MeV}$  and  $\tau(\nu_\tau) \leq 10^3 \text{ s}$ . If these constraints are satisfied then the consistent age is similar to that of Kazanas *et al.*<sup>2</sup> and is,

$$13.8 \text{ Gyr} \leq T_U \leq 15.8 \text{ Gyr}$$

If neutrinos are shown to have electron volt masses then we are forced to conclude  $\rho > \rho_B$  and the less restrictive age limits result.

We thank Keith Olive, Jim Fry, and Gary Steigman for useful discussions. This work was supported by NASA grant NSG 7212.

## Brightening of a hot spot in NCG2903

P. Laques, J.-L. Nieto, J.-L. Vidal, A. Augé & R. Despiaud

Observatoires du Pic du Midi et de Toulouse (Laboratoire Associé au CNRS n° 285), 65200 Bagnères de Bigorre, France

The nuclear region of the Sc galaxy NGC2903 exhibits a very chaotic structure with eight knots, described by Sandage<sup>2</sup> as “giant H II regions”. Others<sup>3,4</sup> called these knots ‘hot spots’. This nuclear region has a very strong blue and UV emission<sup>5–7</sup> and is a 1,420-MHz radio source<sup>8</sup>. Oka *et al.*<sup>1</sup> made photographic and spectroscopic observations of the central region, giving magnitudes and colour indices for the knots which they designated a–g. Physical conditions and stellar content of the 3-arc s central region were investigated by Alloin<sup>10</sup> whereas Turnrose<sup>11</sup> analysed the stellar population in the knot c. The nucleus was identified on near IR photographs<sup>9</sup>. During high resolution—broad band and narrow band—photometric studies of the central region of NGC2903, we have observed and report here that one of the knots (a, according to Oka *et al.*<sup>1</sup>) appears 1.3 mag brighter on plates taken in February 1980 than on a plate taken in January 1978, which agrees with other observations taken<sup>1</sup> in 1966–68.

Our observational material is described in Table 1. The 1978 plate was taken with the Griboval electrographic camera on the 30-inch reflector at the McDonald Observatory. Two other plates (167 P5 and 167 P6) were taken at Pic du Midi Observatory with the 20-mm Lallemand camera attached to the 106-cm reflector on 13 February 1980 as well as a test plate (167 P8) to correct for the S 20 photocathode inhomogeneities. On plates 167 P5 and 167 P6 the knot appeared brighter than on the McDonald plate by between 1 and 1.5 mag. On 18 March, knot a was observed visually with the camera eyepiece to be roughly as bright as the others, whereas in February the object was visually much brighter. The nuclear region as it appeared in January 1978 (McDonald plate with no filter) and in February 1980 (Pic du Midi plate 167 P6 with a V filter) is shown in Fig. 1. de Vaucouleurs has estimated from an electrographic B plate taken on 28 March, 1979 with the 76-cm McDonald reflector that the brightness of spot a was then about the same as in 1978.

The four plates mentioned above were scanned with the PDS microdensitometer at Nice Observatory. The field of the McDonald plate (15 arc min) allowed a reduction procedure following the numerical mapping technique<sup>12</sup> adapted to the interactive CDCA system<sup>13</sup>. The small field of the Lallemand plates (2.5 × 4 arc min) compared with the size of the galaxy did not allow such a procedure and only correction for the inhomogeneities of the photocathode was possible. Thus, the sky density was assumed to be constant and determined in one of the galaxy-density-free corner of the plates. Linearity between plate densities and light intensities were assumed on all plates after checking that densities were in the commonly adopted linear part of the characteristic curves of electrographic plates ( $d < 3$ ). The zero point for the magnitudes was obtained from the integrated V magnitudes measured in various apertures by

Fig. 1 Nuclear region of NGC2903. a, Pic du Midi plate taken with the Lallemand electrographic camera on 13 February 1980, with a V filter. b, McDonald plate taken with the Griboval electrographic camera on 31 January 1978 with no filter, a is the northernmost knot. Scale bar, 5 arc s.

| a    | 14.2                     | 1               | 14.0                              | 1               | 12.7                                   | 1               | —  | 1               |
| c    | 14.3                     | ~0.9            | 14.2                              | 0.83            | 13.9                                   | 0.33            | —  | 0.33            |
| d    | 14.8                     | ~0.6            | 15.0                              | 0.40            | 14.6                                   | 0.18            | —  | 0.18            |

photoelectric photometry, for plate 167 P6, taken with a V filter, as well as for the McDonald plate, taken with no filter. For the latter, this procedure does not lead to a strong error as most of the central intensity of the galaxy comes from the knots which have very similar colour indices ( $B-V \sim 0.4-0.5$ ) (see ref. 1). Unfortunately for the [O III] plate, no absolute calibration can be derived. The derived V magnitudes may have errors of 0.1–0.2 mag. Note that Oka *et al.*'s V measurements for knots a and c correspond respectively to  $5 \times 6$  arc s and  $4 \times 5$  arc s elliptical regions whereas ours correspond respectively to  $5 \times 5$  arc s and  $4 \times 4$  arc s circular regions. As the variations of the sky density under the galaxy are not known for the Pic du Midi plates, the magnitudes presented in Table 2 are just a guide, so the variation of knot a is better perceived intensity-wise relative to knots c and d, whose luminosity might be supposed to be constant: knot a has become ~2.3 times brighter between January 1978 (possibly even March 1979) and February 1980. The [O III] plate corroborates this but cannot tell us much about the nature of this luminosity variation.

Although the knots have an emission spectrum superimposed on a continuum, measurements made with different detector/filter combinations are still comparable because, in one case at least (V band), the spectral bandwidth is very broad and the same as that used by Oka *et al.*<sup>1</sup> Moreover, even in the case of the McDonald plate (with no filter) and the Pic du Midi plate (with a V filter), the intercomparison keeps its full significance because the intensity ratio of knot c compared with knot d remains the same for the two plates (and even for Oka *et al.*), within the measurement errors, whereas the intensity ratio of knot a compared with c or d increases by a factor (~2.3) which is actually significant compared with these errors.

This brightening might be explained by supernova explosion occurring within knot a. From the data in Table 2, we estimate V magnitude of such a supernova at ~13.1. Assuming a distance modulus of 29.43 (distance 7.7 Mpc)<sup>14</sup> gives an absolute magnitude of -16.5 after correction for absorption in our Galaxy ( $A_v = 0.17$ ). This value is compatible with a type II supernova near maximum<sup>15</sup>.

Previous investigations<sup>1,10,11</sup> have led to the description of the nuclear region of NGC2903 as the place of an active phase of star formation with a substantial contribution of young massive stars ionizing the gas. The knot a itself because of its off-centre position was missed in all relevant observations, but we may assume that these considerations are also valid for knot a as well as for hot spot nuclei in general<sup>9-11,16-20</sup>. Therefore, the explosion of a supernova would not be surprising in such a region. Only a few examples are known of supernova phenomena in central regions of galaxies (for example, SN1885 in M31, SN1968 in M83 (ref. 21)). This might be due to

observational bias because an exploding object is harder to detect in a high-surface brightness region, but is probably more frequent than believed. We therefore suggest routine observations of such hot spots to investigate whether such brightenings are the result of supernova outbursts or hot spots are intrinsically variable objects. We hope that other observations of the nuclear region of NGC2903 in 1979–80 will be found to reconstruct the history of this event.

J.-L. N. thanks P. Griboval for the use of the electronographic camera on the McDonald 76-cm telescope. We also thank G. de Vaucouleurs for information on the McDonald electronographic plate taken in March 1979.

## A nonrandom component in cosmic rays of energy $\geq 10^{14}$ eV

C. L. Bhat, M. L. Sapru & C. L. Kaul

Nuclear Research Laboratory, Bhabha Atomic Research Centre, Srinagar, India

We have been studying<sup>1</sup> the distribution of the arrival times of atmospheric Cerenkov light pulses, initiated by cosmic rays of energy  $\geq 10^{14}$  eV. We have now detected a nonrandom component for time separations  $< 40$  s, and here we discuss the possibility that it has a point-source origin.

The light pulses were detected at Gulmarg (altitude 2,743 m), India, on clear moonless nights, by two, coincidentally operating wide-angle photomultipliers (EMI 9545 B; viewing angle with respect to zenith,  $50^\circ$ ). Each Cerenkov light pulse, identified by its characteristic shape, was recorded with its occurrence time by a logic system with a dead-time of  $\leq 100$  ms. The amplitude discrimination levels of both the detector channels were held constant above the shot-noise fluctuations in the night-sky background light. The detection system was regularly checked with a standard light-pulsar to ensure that the photomultiplier and amplifier gains remained unaltered. Between June 1976 and June 1978 observations were possible for 180 h and 9,879 events were recorded, corresponding to an average rate of  $\sim 55$  events per h. The observed hourly rates show a fairly symmetrical scatter around this value.

Using all the data, we have plotted the arrival-time distribution of the events, that is, the distribution of time-separation  $t$  between consecutive events on a 10-s bin size (Fig. 1). The smooth curve shows the expected exponential distribution of the arrival times assuming that the time of occurrence of the events is completely random; the inset to Fig. 1 represents standard deviations of the frequencies of the events with respect to the fitted curve. Deviations at  $\geq 5\sigma$  are apparent for  $t \leq 40$  s, the implied overabundance constituting  $\sim 12\%$  of the total number of events.

The possibility that this overabundance was of instrumental origin was examined by subjecting the detection system to a random time-series simulation, in which the system photomultipliers were simultaneously exposed to light pulses from a pair

Fig. 1 The histogram shows the observed distribution of time separations,  $t$ , between consecutive events on a 10-s bin-size. Error bars up to  $t = 50$  s are also shown. The smooth curve is the exponential fit to this histogram. Standard deviations,  $\sigma$ , of the event frequencies with respect to the fitted curve are shown in the inset.

Fig. 2 *a* Shows the rate per h of events as a function of the RA values. Events with  $t \leq 40$  s only are included, *b*, Same as *a* except that events with time separations of 41–450 s alone are included in the distribution.

of LED lamps. The flashing rate of the lamps was so controlled by a random pulse generator that pulses with time separations of 1–500 s were possible. The output from the detection system in this case was found to reproduce quite accurately the expected exponential variation in time. Likewise, solar-terrestrial origin of the overabundance also seems improbable because the event rates did not exhibit systematic solar time variations and also because the arrival-time distributions for days of high and low values of the geomagnetic disturbance index  $A_p$ , when considered separately, reproduced the excess contribution for  $t \leq 40$  s to the same extent. Clearly, also, at these energies the effect cannot be understood in terms of the interplanetary magnetic field fluctuations. Furthermore, Baadino *et al.*<sup>2</sup>, following our earlier work<sup>1</sup>, have also observed a significant extra contribution for  $t \leq 37.5$  s in muons produced by cosmic-ray primaries of energy  $\sim 5 \times 10^{13}$  eV. Therefore, the observed excess is not peculiar to the optical method of detecting high-energy cosmic rays.

To find whether the observed excess has a sidereal association, the rates of two subsamples with  $t \leq 40$  s and  $40 < t \leq 450$  s, constituting 5,033 and 4,846 events, respectively, were plotted (Fig. 2) as a function of right ascension (RA), the RA value of an event being derived from its absolute occurrence time. It is clear that, whereas events with  $t > 40$  s do not show a directional preference (Fig. 2*b*), those with  $t \leq 40$  s, constituting the excess region, exhibit a statistically significant peak at  $RA = 05 \pm 03$  h (Fig. 2*a*). To investigate this association further, events with  $t \leq 40$  s were divided into two 1-year subsamples, and the directional enhancement at  $RA = 05 \pm 03$  h was observed in each of them separately. The large width of the peak in Fig. 2*a* is compatible with the response function of our wide-angle detection system for Cerenkov light from EAS<sup>3</sup>. The large angular response of the detection system was also responsible for our observation of a significant excess of events for  $t \leq 40$  s even for the period December 1978–January 1979, when, during a search for optical bursts from primordial black-hole explosions<sup>1,4</sup>, a similar experiment was carried out simultaneously at Gulmarg and 30 km away at Srinagar (altitude 1,524 m). Figure 3 shows the sidereal distribution of the event rates for  $t \leq 40$  s for the two data samples obtained from this experiment. It is apparent that the rates in both the samples show a clear rising trend beyond 22 h RA, which, if data beyond January 1979 were available, would probably reproduce the peak observed in Fig. 2*a* and so provide additional confirmation

Fig. 3 Hourly rates of events with  $t < 40$  s as a function of RA for December 1978–January 1979. Data recorded at Gulmarg (a) and Srirangar (b).

regarding the sidereal association of the excess. In view of this, it is useful to determine whether this excess contribution is due to a high flux of  $>10^{14}$  eV charged particles or to  $\gamma$ -rays coming presumably from a cosmic source with  $RA \approx 05 \pm 03$  h.

For a cosmic-ray proton of energy  $>10^{14}$  eV, the gyro-radius in the galactic magnetic field is  $>0.03$  pc, which is quite small relative to the typical scale-lengths of the interstellar magnetic field irregularities, generally believed to be  $\sim 1$ – $100$  pc (ref. 5). According to the compound diffusion model<sup>6</sup>, a cosmic-ray proton follows the field lines for distances less than  $1$ – $100$  pc and is then transferred to other field lines in a random manner. Accordingly, charged particles coming from a galactic source, a

few kpc away, suffer scattering in the interstellar space and are not, therefore, expected to retain original source direction. On the contrary, one may, following Barrowes<sup>7</sup>, hypothesize that there are very few small-scale irregularities in the interstellar magnetic field in the direction of the source, so that charged primaries, gyrating around a quite well ordered magnetic field, reach us without undergoing sufficient randomization. The observed directional enhancement is, however, more easily understood if one assumes that the source is emitting  $\gamma$ -ray photons of energy  $>10^{14}$  eV, which the present detection system cannot distinguish from charged primaries. Several instances of discrete source anisotropies have been reported<sup>8,9</sup> including the point sources at  $RA = 6$  h, dec.  $\delta = 6^\circ \pm 1^\circ$  and at  $RA = 5$  h,  $\delta = 0.5^\circ$ .

If this view of the point-source origin of the excess contribution is valid, its time-structure will probably provide further information on the nature of the source. Accordingly, we plotted (Fig. 4a) the arrival-time distribution of events with RA values between 22 and 9 h only, which correspond to the abscissa limits of the peak in Fig. 2a. The distribution of the arrival times of the excess events, plotted in Fig. 4b, shows a significant peak at  $\sim 4$  s, suggesting that there is a departure from time-randomness and that in the case of source events,  $t \sim 4$  s is more probable than smaller arrival times, conceivably a manifestation of some kind of modulation due to the source. Extensive theoretical work by Ostriker and Gunn<sup>10</sup> and others shows that indeed a rotating neutron star is capable of producing cosmic rays of energy  $>10^{14}$  eV. In view of this and the fact that the excess contribution peaks at  $\sim 4$  s, it is tempting to infer that the source may be the pulsar PSR 0525+21, which has a period of 3.7 s and lies at a distance of 1.6 kpc (ref. 11). If so, it may be argued that high-energy particles, probably  $\gamma$  rays, are emitted randomly in time from a restricted region on or near this pulsar. The effect of the pulsar rotation period of 3.7 s would be seen by an Earth-bound observer as an enhanced frequency for  $t$  near 3.7 s and its harmonics relative to the other arrival times, which would be reduced in frequencies depending on the angle of the emission cone. Obviously, the event rate from the source cannot depend on the pulsar rotation period alone but also depends on distance, intrinsic flux and other emission characteristics of the source.

One may surmise, alternatively, that intense particle bursts are emitted towards the Earth with the pulsar period of 3.7 s. As the observed average interval between consecutive events is  $\sim 1$  min, that is, nearly 16 pulsar periods, one would rule this out

Fig. 4 a, The histogram shows the distribution of time separations,  $t$ , on a 1-s bin size. Events with RA values 22–9 h are included in this distribution. The smooth curve is the exponential fit to this distribution. b Shows the distribution of extra events obtained from a as a function of  $t$ .

unless an additional restriction is imposed that the bursting activity lasts only for a fraction of the total observing time. Further experiments in the Northern Hemisphere by air shower arrays and optical detection systems, designed with improved angular resolution and a bias towards photon-initiated showers, would be helpful in this connection.

## Extremely relativistic electron-positron twin-jets form extragalactic radio sources

The extended extragalactic double radio sources—quasars, BL Lac-type-objects (blazars), and radio galaxies—are commonly interpreted as synchrotron sources in which extremely relativistic electrons gyrate in enhanced magnetic fields. The detection of narrow emission bridges between hot spots inside these sources and the centre of an intermediate galaxy has strongly favoured the existence of a continuous power-line feeding the extended source<sup>1,3,5</sup>. Such beams may be a universal phenomenon occurring in many—if not all—massive galaxies, including our own<sup>4</sup>. But whereas early interpretations involved low-frequency electromagnetic waves and/or relativistic particle beams, more recent work favoured non-relativistic ( $\beta < 10^{-1}$ ) (refs 3, 6–8), or mildly relativistic ( $\gamma < 10$ ) (refs 9–11) bulk velocities for the power supply. In particular, non-relativistic bulk velocities  $c\beta$  have been derived from estimates of the involved kinetic energy densities  $u$  and mass densities  $\rho$  in the form  $\beta \approx (2u/\rho)^{1/2}$ . This can lead to large underestimates of  $\beta$  when  $\rho$  is derived from Faraday rotation and depolarization data, because the observed jets are likely to have a two-fluid structure, with light relativistic plasma streaming inside of heavy ‘walls’ of thermal matter, or traversing ‘swarms’ of heavy quasistatic filaments<sup>12</sup>. We suggest here that these beams consist of extremely relativistic electrons and positrons, of typical Lorentz factor  $\gamma \geq 10^2$ .

The power streaming in the jets must be liberated inside the galactic nucleus, from matter spiralling into the central powerhouse. This power  $\dot{E}_{\text{lobes}}$  should be a small fraction  $\eta$  ( $\ll 1$ ) of the total liberated power  $\dot{E}_{\text{tot}}$  because of its comparatively low entropy. The power  $\dot{E}_{\text{tot}}$  in turn is a small fraction  $\epsilon$  ( $< 1$ ) of the accreted mass-energy rate  $\dot{M}_{\text{in}}c^2$ , where  $\epsilon \leq 0.1$  is suggested by black-hole models whereas hydrogen burning<sup>13</sup> (of  $\leq 20\%$  of the fuel) amounts to  $\epsilon \leq 2 \times 10^{-3}$ . The rest mass rate  $\dot{M}_{\text{lobes}} = \dot{E}_{\text{lobes}}/(\gamma - 1)c^2$  injected into the lobes cannot exceed the fuel-

ling rate  $\dot{M}_{\text{in}}$ , hence

$$1 < \dot{M}_{\text{in}}/\dot{M}_{\text{lobes}} = (\gamma - 1)/\epsilon\eta \quad (1)$$

or  $\gamma > 1 + \epsilon\eta$ ; which would imply, for non-relativistic values of  $\beta = (1 - \gamma^{-2})^{-1/2}$ :

$$\beta > (2\epsilon\eta)^{1/2} = 1.4 \times 10^{-2}(\epsilon\eta/10^{-4})^{1/2} \quad (2)$$

that is slow bulk speeds  $c\beta$  of the beam material imply a small ‘beaming efficiency’  $\eta$ . But  $\eta$  is likely to be above  $10^{-2}$ . To see this, note that  $\dot{E}_{\text{lobes}}$  can exceed the luminosity  $L_{\text{lobes}}$  of the lobes when most of the beam energy is stored in relativistic gyrations, and that a substantial fraction of  $L_{\text{lobes}}$  can be emitted near optical frequencies<sup>14</sup>, whereas the compact nuclear source is expected to emit its excess energy instantaneously as high surface-brightness electromagnetic radiation, mainly between IR and  $\gamma$ -ray energies. We thus have

$$\eta = \dot{E}_{\text{lobes}}/\dot{E}_{\text{tot}} \geq L_{\text{lobes}}/L_{\text{core}} = 10^{-2 \pm 2} \quad (3)$$

the latter for well-studied sources like 3C273, Cen A, Cyg A, and from source statistics. Equation (2) then implies beam particle velocities in excess of  $10^9 \text{ cm s}^{-1}$ .

A second estimate of  $\beta$  derives from the speed at which the lobes of double sources separate. This speed has been estimated from the core-hot spot separations<sup>15,16</sup> to be of the order of  $v_r = 10^{-1 \pm 0.3}c$ . Similar values for  $v_r$  can be obtained from force balance calculations<sup>12</sup>. The flow inside the jets must reach the outer ends of the radio lobes, hence its velocity must exceed  $v_r$ .

The flow inside the (almost free) jets is expected to be supersonic, although it must go subsonic at its termination point. Consequently,  $v_r$  is even a lower limit on the sound speed of the hot-spot material, whose temperature  $T_+$  must therefore exceed  $m v_r^2/3k \geq 10^{10} \text{ K}(m/10^{-24} \text{ g})$ . Were the jets subsonic,  $T_+$  would at the same time be a lower limit to the jet temperature. For a supersonic jet, on the other hand, there must be an inner shock surface towards the ambient medium where the flow passes from supersonic to subsonic. One can then relate the post-shock temperature  $T_+$  to the pre-shock temperature  $T_-$  and get a more severe lower limit to the jet velocity.

If we assume that the jet velocity were sub-relativistic, its pre-shock sound speed  $v_{s,-}$  would be related to its post-shock sound speed  $v_{s,+}$  by<sup>17</sup>

$$v_{s,-}/v_{s,+} \approx [(\Gamma + 1)/(\Gamma - 1)]^{1/2}(p^-/p^+)^{1/2} \quad (4)$$

where  $p^\pm$  are the pressures before and behind the shock respectively, and  $\Gamma$  is the adiabatic index. The pressure ratio  $p^+/p^-$  is unlikely to exceed 30; it can be estimated from the brightness ratio at different parts of the hot spot: In a few cases, a scintillating component has been found inside the hot spot whose inferred pressure is about 10 times higher than that of its surroundings<sup>18,19</sup>. For  $\Gamma \leq 5/3$ , equation (4) therefore yields  $v_{s,-}/v_{s,+} \geq 0.6$ . But  $v_{s,+}$  must exceed the post-shock flow velocity  $v^+$  which is larger than the lobe velocity  $v_r$ , hence  $v_{s,-} \geq 0.6 v_r \geq 0.06 c$ , corresponding again to a pre-shock temperature  $T_- \geq 10^{10} \text{ K}(m/10^{-24} \text{ g})$ . This lower limit conflicts with independent temperature estimates<sup>3</sup> ( $T_- \leq 10^7 \text{ K}$ ) of the jet material, that is excludes non-relativistic jet velocities. Also, adiabatic cooling in the jet would imply extremely relativistic temperatures near the origin.

Relativistic bulk velocities of the beam material are also suggested by the following independent observations whose details are discussed elsewhere<sup>12</sup>:

(1) Roughly half of the strongest compact extragalactic radio sources show intermittent superluminal expansion, on scales between 10 and  $10^2$  light yr, with apparent expansion speeds ranging up to  $40 c$  (for 3C454.3)<sup>20,21</sup>. These speeds must, of course, be phase velocities, but all reasonable models involve relativistic bulk velocities<sup>22</sup> of the beam material.

(2) In most cases, the observed jets are one-sided, both in radio, optical, and X rays. Even in sources with a large inclination angle of their axis, like Cyg A, the VLBI structure is one-sided<sup>21</sup>. Relativistic beaming is the only convincing explanation<sup>12</sup>.

\* Permanent address: Tata Institute of Fundamental Research, PO Box 8, Ootacamund-643001, India.

(3) The largest extragalactic radio sources<sup>23</sup> have unprojected tails of length  $r \geq 3 \times 10^7$  light yr, and their central engines are still active. A non-relativistic power supply would make the central engine very old, and its fuel demand very high.

(4) When a beam of magnetized plasma is blown into some ambient plasma, its hot-spot develops at the far end of the resulting jet only if its mass density is much lower than that of the surroundings. In the opposite case, the hot-spot develops at the near end. But a lower mass density implies a higher sound speed (than some  $10^8$  cm s<sup>-1</sup>), and an even higher (supersonic) bulk velocity.

(5) The beams of most sources are bent, in particular those of the head-tail galaxies. The standard explanation of bent beams uses ram pressure confinement<sup>5,7</sup>, in which case the bending angle is proportional to the bulk velocity of the power supply (for a given power). Non-relativistic supply velocities would in some cases ask for implausibly high ram pressures of the intergalactic medium.

(6) For non-relativistic power supply velocities, all the relativistic electrons in the jets and lobes would have to be accelerated *in situ*. According to the second law of thermodynamics, this is only possible for a small fraction of the total power.

(7) The observed stability of the (often curved!) jets, on length scales exceeding  $10^5$  light yr, poses problems for non-relativistic bulk velocities<sup>12</sup>.

We shall now suggest that the beams consist of electrons and positrons, with ions being energetically insignificant. Consider if there were no positrons, and  $n_e$  was the particle number density of the electrons,  $n_i$  the corresponding density of the (positive) ions. Charge neutrality in the beam implies  $n_e = n_i$ . The ratio  $\xi$  of energy densities in ions and electrons then reads

$$\xi = n_i \gamma_i m_i c^2 / n_e \gamma_e m_e c^2 \geq 1,836 \gamma_i / \gamma_e \quad (5)$$

where  $\gamma_i$ ,  $\gamma_e$  are the average Lorentz factors of ions and electrons respectively.  $\xi$  should not exceed unity by much because the power stored in ions is invisible, and the lobe power  $\dot{E}_{\text{lobes}}$  inferred from the synchrotron radiation of the electrons ought to stay significantly below the core power  $\dot{E}_{\text{core}}$  not to violate the second law of thermodynamics, see equation (3). But then equation (5) implies large Lorentz factors for the electrons:  $\gamma_e \geq 2 \times 10^3 \gamma_i$ , larger than inferred from equipartition estimates for the energetic peak of the electron distribution. In other words, if the charge of the electrons were neutralized by the charge of ions, the necessary inequality  $1 \gg \eta = \dot{E}_{\text{lobes}} / \dot{E}_{\text{core}}$  would be violated, either by a power excess in the ions, or by a significant deviation from equipartition (between magnetic and electron kinetic energy).

This argument can be strengthened by interpreting the frequent and pronounced one-sidedness of the jets as being due to extreme bulk velocities ( $\gamma_{\text{bulk}} \geq 10^2$ ) of the electrons radiating when their path is obstructed<sup>12</sup>, rather than as being due to mildly relativistic motion at a small beam inclination angle: The bulk velocities of oppositely charged particles cannot differ by more than  $10^{-11} c$  ( $\dot{E}_{\text{lobes}} / 10^{44} \text{ erg s}^{-1}$ )<sup>1/2</sup> because their relative motion would otherwise generate higher than equipartition magnetic fields. Consequently, the bulk Lorentz factor of the electrons must equal  $\gamma_i$ , and the condition  $\gamma_e \geq 2 \times 10^3 \gamma_i$  would imply  $\gamma_e \geq 2 \times 10^5$ , that is extreme deviation from equipartition.

There are other indications of the near-absence of ions in the beams<sup>12</sup>; briefly they are:

(1) The direct supply of extremely relativistic electrons to the lobes avoids the difficulty of upgrading thermal energy of a mildly relativistic plasma to much higher energies of most of the electrons.

(2) No booster of two relativistic electron-ion plasma beams is known; the situation is different for an electron-positron plasma wave-riding a strong spherical wave, and focused by a magnetic pinch<sup>13</sup>.

(3) The smallness of observed Faraday rotation in compact sources rules out the presence of a significant fraction of low-

energy electrons, but does not rule out a neutral electron-positron plasma<sup>27</sup>.

(4) It has been suggested that the relativistic wind of the Crab pulsar consists of an extremely relativistic electron-positron plasma<sup>24,25</sup>. Galactic centre sources are likely to follow a similar working scheme<sup>13</sup>.

(5) The observed positron annihilation radiation from our galactic centre<sup>26</sup> is reported to exceed that likely to be injected by young pulsars by roughly two orders of magnitude. An active past of our galactic centre would yield a plausible interpretation.

## Flux tube dynamo approach to the solar cycle

Manfred Schüssler

Universitäts-Sternwarte, Geismarlandstraße 11,  
D-3400 Göttingen, FRG

In the past two decades dynamo models of solar activity and the physical foundations of the solar cycle have become acceptable. However, recent observations revealing the concentrated form of photospheric magnetic flux<sup>1</sup>, the distribution and cyclic appearance of X-ray bright points<sup>2,3</sup> and ephemeral active regions<sup>4</sup>, as well as the discovery of sunspot brightness variations during the solar cycle<sup>5,6</sup>, have raised some questions about the dynamo theory of solar activity<sup>7</sup>. Both observation and theory<sup>8</sup> suggest that most of the magnetic flux in the solar convection zone is in the form of concentrated isolated magnetic flux tubes. The turbulent dynamo theory<sup>9,10</sup> has, therefore, to be modified and attempts have been made to include concentrated fields<sup>11</sup>. Nevertheless, the dynamo problem for a convective medium pervaded by concentrated flux tubes, the 'flux tube dynamo', has not yet been solved. The problem is to regenerate the poloidal magnetic field out of which toroidal field is produced by differential rotation. Here the consequences and the structure of the resulting cycle are considered if a field regeneration process operating on flux tubes is assumed. A calculation similar to Leighton's magneto-kinematic model<sup>12</sup> shows that a flux tube dynamo model can operate and reproduce the essential features of the solar cycle. It can also explain the cyclic variation of sunspot brightness and ephemeral active regions.

I conjecture that the variation of sunspot brightness and appearance of ephemeral active regions (EAR) or X-ray bright points (XBP) is caused by different age of the basic flux tubes. If EAR are interpreted as products of 'shredding' of big flux tubes by violent convective motions, older flux tubes will suffer longer

from this influence than younger tubes. Consequently, they yield more EAR and some may be totally disrupted before they reach the photosphere. The effect of age on sunspot brightness is not as obvious because of the lack of a detailed theory of the deep structure and cooling of sunspots. As sunspots are already cool when they appear in the photosphere, the cooling 'machine' must work beneath it. A plausible mechanism is the formation of loops with subsequent adiabatic downflow within the solar convection zone through a convective instability. If this happens at the beginning of the tube's existence it will subsequently be heated by radiation (and possibly convection of reduced efficiency because of the magnetic field). The older a flux tube, the longer the time available for heat exchange: emerged older tubes will appear brighter than younger ones. If the convective instability happens in the upper (more superadiabatic) layers of the convection zone, the initial conditions depend on flux tube age: older tubes are more severely distorted and 'shredded' by convective motions and possibly the instability will not be as efficient in cooling as for younger tubes. Finally, distorted old tubes might produce more umbral dots after emerging as sunspots, leading to a brighter appearance of the umbra when observed with normal resolution.

As long as the subphotospheric cooling of magnetic flux is not well understood the above arguments are speculative. Nevertheless, convection causes old flux tubes to be physically different from young tubes and the above considerations suggest that they are less coherent and not as cool as younger tubes.

Age differences between flux tubes can arise as follows. Consider a shear region of strong differential rotation where toroidal flux is produced out of a poloidal magnetic field. The flux tubes built by this process leave the shear region due to their magnetic buoyancy depending on the magnetic field strength: stronger fields are more buoyant and rise faster. The stronger the poloidal field, the faster the toroidal field increases and the faster (and younger) the flux tube leaves the shear region<sup>13</sup>. If the poloidal field strength varies during the cycle, the age of the flux tubes which appear in the photosphere also shows a cyclic variation.

To study the value of the age hypothesis and to get some insight into the behaviour of a flux tube dynamo I have investigated a simple one-dimensional model.

Consider a sphere with a thin shear region due to differential rotation  $\partial\Omega/\partial r$ , idealized by a shell at  $r = r_1$ . In the axisymmetric case, the magnetic field in the shell only depends on the colatitude  $0 \leq x \leq \pi$  and time  $t$ .

Fig. 1 A synthetic butterfly diagram. The latitude of appearance of flux tubes is plotted against time. Their activity lasts for months and leads to the broad wings of observed butterfly diagrams. Tubes appearing in high latitudes are weak and old: they are probably disrupted totally and do not build big active regions with spots.

Fig. 2 Activity index and flux tube age: oldest flux tubes appear during activity minimum and vice versa. The age as a function of time shows a striking similarity to the variation of sunspot brightness and the number of XBP in time<sup>5,6</sup>.

The toroidal field is determined by the  $\phi$ -component of the induction equation at  $r = r_1$ :

$$\frac{\partial B_\phi}{\partial t} = B_r \cdot \sin(x) \cdot r_1 \cdot \left( \frac{\partial \Omega}{\partial r} \right)_{r=r_1} \quad (1)$$

We define a critical field strength,  $B_c$ , comparable with the equipartition with the convective kinetic energy. For  $B_\phi \gg B_c$  convection is suppressed within the flux tube, the tube has an 'identity' and we start to count the age,  $A$ . The tube tends to leave the shear region because of its buoyancy with a probability assumed to depend on the product of field strength and age,  $B_\phi \cdot A$ . We allow for a random component in the cycle by defining the eruption probability  $P$  in the following way, using constants  $C_1, C_2$ :

$$\begin{aligned} 0 &\leq B_\phi \cdot A < C_1: P = 0 \\ C_1 &\leq B_\phi \cdot A < C_2: P = \frac{B_\phi A - C_1}{C_2 - C_1} \\ C_2 &\leq B_\phi \cdot A: P = 1 \end{aligned} \quad (2)$$

Whether the tube leaves the shear region or not is determined by a random number generator, according to the above defined probabilities. The relevant poloidal field component,  $B_r$ , is regenerated by an unspecified dynamo process yielding a current parallel (Northern Hemisphere) or antiparallel (Southern Hemisphere) to the toroidal field  $B_\phi$ . The radial component of the field produced by this current for a flux tube situated at  $x = x_0$  is assumed to have the triangular profile  $R(x - x_0) = R(\bar{x})$ , for simplicity.

$$R(\bar{x}) = \begin{cases} \frac{\bar{x}}{x_m} & \text{for } |\bar{x}| \leq x_m \\ \frac{\bar{x} - \text{sgn } \bar{x} \cdot D}{x_m - D} & \text{for } x_m \leq |\bar{x}| \leq D \\ 0 & \text{for } D \leq |\bar{x}| \end{cases} \quad (3)$$

The parameters  $x_m$  and  $D$  define the location of the maximum and the total extension of the poloidal field produced by one flux tube, respectively. Therefore,  $D$  is a measure for the efficiency of (turbulent) diffusion in dispersing the weak poloidal fields spatially. The regeneration term for the poloidal field coming from one flux tube at  $x = x_0$  is hence:

$$r(x, x_0) = \alpha(x_0) B_\phi(x_0, t) R(x - x_0) \quad (4)$$

where  $\alpha(x)$  measures the strength of the regeneration process. As the role of rotation and Coriolis forces seem essential for any relevant mechanism we take  $\alpha = \alpha_0 \cos x$ . Now consider a distribution of  $N$  flux tubes at  $x = x_1, \dots, x_N$ . The poloidal field at the location  $x_i$  of one flux tube which is necessary for the amplification of  $B_\phi(x_i)$  throughout equation (1) is given by

$$\frac{\partial B_r(x_i)}{\partial t} = -\gamma B_r(x_i) + \sum_{j=1}^N r(x_i, x_j) \quad (5)$$

The contributions of all flux tubes to the poloidal field are summed and  $-\gamma B_r$  is a simple dissipation term. (A dissipation term for the toroidal field has not been included in equation (1) because turbulence is assumed to be suppressed within the flux tubes and the molecular diffusivity is neglected. This is not possible for the much weaker poloidal field.)

Equations (1) and (5) have been integrated forward in time, paying attention to flux eruption determined by equation (2) through random numbers. In spite of the considerable number of free parameters, the results sensitively depend only on a few of these. The quotient  $\alpha/\gamma$  determines whether the dynamo is excited or not: a critical value has to be exceeded. The other sensitive parameter is  $D$ , the half width of the regenerated poloidal field due to one flux tube. To get a butterfly diagram comparable with the observations  $D \geq 0.1 \pi$ , otherwise the butterfly wings overlap severely or the large-scale structure changes totally to irregular fluctuations. Therefore, even a flux tube dynamo depends on strong turbulent diffusion allowing for effective superposition of the poloidal field contributions of the individual flux tubes.

The results for a model with  $D = 0.125 \pi$ ,  $x_m = 0.025 \pi$  are shown in Figs 1 and 2. Figure 1 shows a 'synthetic' butterfly diagram in which the latitude of erupted flux tubes is drawn against eruption time. Numbers indicate positive field strength (in arbitrary units), letters negative field strength ( $A \triangleq -1$ ,  $B \triangleq -2 \dots$ ). Although only the time of the first appearance of a flux tube is shown, activity caused by it can last for months. This must be remembered when Fig. 1 is compared with observed butterfly diagrams showing broad wings. We can also define an activity index by monitoring the number and field strength of erupting flux tubes per time interval. This index is given in Fig. 2 together with the age of erupted flux tubes as a function of time. Looking first on the activity index, we observe a fast rise of the cycle, followed by a slower descent towards the minimum in accordance with the typical behaviour of the sunspot cycle (the secondary maximum is possibly accidental).

The cyclic variation of flux tube age seems to be very significant. The youngest tubes appear at activity maximum, flux tube age increases gradually during the decline of activity and reaches a maximum at activity minimum, followed by a sharp falling-off during the rise to the activity maximum. This variation is almost identical to the behaviour of sunspot brightness in time<sup>5,6</sup> and supports our hypothesis. Moreover, the anticyclic variation of XBP and EAR can be interpreted as an effect of age, too: older and therefore more severely 'shredded' tubes appear about activity minimum. It is quite plausible that the oldest of them are disrupted totally and only appear as XBP and EAR in high latitudes as the first messengers of the new cycle<sup>4</sup>. This would also decrease the latitude at which the first spots of a new cycle appear and thus remove the excess extension of the butterfly wings in Fig. 1 (XBP and EAR are not included in the classical activity measures, sunspot numbers and butterfly diagram). The problem of activity appearing in high latitudes was encountered by most dynamo models and was usually dealt with by ad hoc arguments.

Results from this crude and simplified model are thus very encouraging: the variations of sunspot brightness and of the appearance of XBP and EAR can be interpreted as an effect of age of the basic flux tubes. In considering the 'solar clock' proposed by Dicke<sup>14</sup> and the Maunder minimum, the present calculations, Leighton's and many other dynamo models show that non-linear dynamo action has a self-stabilization of phase, even if random fluctuations are allowed for.

Phase fluctuations in certain activity measures as sunspot number or the D/H indicator can easily be interpreted as fluctuations in the ratio of magnetic flux appearing in EAR to the flux appearing in big active regions with spots and flares, that is fluctuations of the amplitude of dynamo action (poloidal field), not phase. As the dynamo operates deep down in the convection zone with constant phase, then phase fluctuations of surface activity do not lead to a random walk of phase: the dynamo itself is the solar chronometer. The low sunspot numbers during the Maunder minimum may not be interpreted by a total stop of the 'machine', but can be understood as a period of weaker poloidal field causing the production of older flux tubes which have been disrupted by convection and only appeared as EAR, not sunspots. The dynamo has operated all the time and no phase problems arise at the end of this period.

## X-ray diffraction from adsorbed iodine on graphite

M. Fleischmann, P. J. Hendra & J. Robinson

Department of Chemistry, The University, Southampton SO9 5NH, UK

Our knowledge of surface structure at the solid-vacuum interface has been acquired largely through high-vacuum analytical techniques. Unfortunately these may not be applied *in situ* to solid-liquid or solid-high-pressure gas interfaces which are of greater practical importance. *Ex situ* investigations have been made but the transfers involved probably result in surface restructuring. It is therefore apparent that *in situ* techniques are required. Raman spectroscopy<sup>1</sup> is applicable but lacks versatility, whilst neutron diffraction<sup>2</sup> and SEXAFS<sup>3</sup> are promising but depend on a reactor and synchrotron respectively. X-ray diffraction, on the other hand, is routinely performed and the theory is well developed though it has been assumed to be insensitive to surfaces. We report here the first observation of X-ray diffraction from a two-dimensional adsorbate formed at the solid-liquid interface,  $I_2$  on carbon, using position-sensitive detection to enhance sensitivity.

The adsorption of  $I_2$  from aqueous  $KI_3$  solution, on carbon was chosen as a test system as it has been widely studied and also because it is particularly suited to X-ray investigation in view of the large scattering cross-section of  $I_2$  with respect to carbon. The adsorbent chosen was Papyex; a graphitic material (in the form of 0.15-mm thick sheets) in which approximately half the graphite basal planes lie within a few degrees of parallel to the surface. This material has recently found wide use in neutron

**Fig. 1** Diffraction patterns of Papyex in: *a*, 0.1M KI, in-plane geometry; *b*, 0.02M I<sub>2</sub> in 0.1M KI, in-plane geometry; *c*, 0.02M I<sub>2</sub> in 0.1M KI, out-of-plane geometry. The sample thickness for *a* and *b* was 0.3 mm and for *c* 0.8 mm. The count time was 4,000 s.

diffraction studies of gas-phase adsorption<sup>4</sup> and has a surface area of  $\sim 20 \text{ m}^2 \text{ g}^{-1}$ . Whilst higher surface area graphites are available, the preferred orientation of the graphite flakes in Papyex make it particularly useful; one can perform diffraction experiments either in the in-plane geometry (X-ray beam normal to the surface) probing primarily correlations in the plane of the surface or (by turning the sample through 90°) in the out-of-plane geometry, probing correlations perpendicular to this plane.

In the experiments reported here, Papyex sheets were equilibrated for 48 h with aqueous solutions of I<sub>2</sub> in KI before transfer to a cell fitted with Mylar windows for the entrance and exit of the X-ray beam. A stack of two Papyex sheets was used and the cell was designed to minimize the thickness of solution through which the beam passed.

The scattering from an adsorbate is obviously very small compared with the total observed (the substrate and H<sub>2</sub>O molecules contribute the major portion). A high photon count is therefore necessary to obtain adequate signal-to-noise ratios. This precludes the use of conventional counting techniques because of the prohibitive times involved. However, the past few years has seen the introduction of X-ray position-sensitive proportional counters (PSPC) which have proved very useful in biological applications where low exposure times are desirable<sup>5</sup>. A PSPC similar to that described by Borkowski and Kopp<sup>6</sup> was used in this study. Briefly, the anode is a high-resistance wire, parallel to the entrance window, which behaves as a distributed delay line. The position on the wire of the charge pulse caused by the X-ray photon is determined by the risetime of the pulse at each end of the wire and the output of the signal-processing electronics is a pulse, the height of which is related to the position of the X-ray event. These pulses are then sorted by a multichannel analyser which displays the intensity-position spectrum of the diffracted X-rays. The detector used had a

20-cm active length, a window height of 1 cm and a depth of 1 cm. A copper anode X-ray tube operating at 40 kV, 20 mA was the source.

Typical diffractograms are shown in Fig. 1 for Papyex in I<sub>2</sub>-free KI solutions and with a monolayer coverage of I<sub>2</sub>, both for in-plane geometry, and for monolayer coverage in the out-of-plane geometry. The peak at  $2\theta = 26.6^\circ$  on all the diffractograms is the (002) diffraction of graphite, whilst the broad peak at  $2\theta = 44.2^\circ$  is that for the (100) and (101) planes. The peak at  $2\theta = 16.3^\circ$  is due to the Mylar windows as is the shoulder on the low-angle side of the (002) diffraction. The peak in Fig. 1*b* at  $2\theta = 19.6^\circ$  is assigned to the (10) diffraction of a two-dimensional layer of hexagonally close-packed adsorbed I<sub>2</sub> molecules. Figure 2*a-d* shows this region of the diffractogram in more detail for increasing values of I<sub>2</sub> coverage (as determined by titration techniques which indicated a Langmuir-type isotherm with a maximum coverage of  $3.9 \times 10^{-2} \text{ g I}_2 \text{ per gC}$ ). Whilst the position of the (10) diffraction is independent of coverage, the intensity is proportional to it. This indicates that the forces between the adsorbed I<sub>2</sub> molecules are attractive and that the adsorbate is present as islands. From the half width of the (10) peak the size of these islands may be estimated<sup>7</sup>; for the coverage range 0.1–1.0 this was found to be constant at  $110 \pm 20 \text{ \AA}$ ; a value identical to the crystallite size for adsorbed Kr on Papyex as determined by neutron diffraction<sup>4</sup>. This dimension has been attributed to the size of the graphite flakes. It is, therefore, better to regard the iodine adsorption process as a higher-order phase transition. The position of the (10) peak, in the Warren formalism<sup>7</sup> for diffraction from a two-dimensional structure corresponds to a layer spacing of 4.6 Å, which in the hexagonally close-packed structure gives a nearest-neighbour distance of 5.3 Å, which is slightly less than the value at the

**Fig. 2** Details of diffractograms of Papyex, equilibrated with I<sub>2</sub> solutions in KI, between  $2\theta = 15^\circ$  and  $20^\circ$ . The coverages were: *a*, 0; *b*, 0.05; *c*, 0.7; *d*, 1.0.

minimum of the Lennard-Jones potential, 5.6 Å. The calculated nearest-neighbour distance, in conjunction with the value of the maximum coverage, gives the surface area of Papyex as 22 m<sup>2</sup> g<sup>-1</sup>, in close agreement with values obtained by other methods.

While these results were obtained for a favourable system, they indicate that X-ray diffraction can be successfully applied to adsorption studies in condensed media. It is inherent in these studies that there will always be a large background signal arising from scattering by the solution, therefore, accurate background subtraction techniques are required. These subtractions are difficult because of the large X-ray absorption cross-sections of potential adsorbates. This is overcome in diffraction studies of gas phase adsorption by recording the background at a temperature where the adsorbate is present as a 'liquid' and not an ordered array, but such a technique is not possible with condensed phases. In electrochemistry, however, it is possible to modulate the electrode potential and therefore accurate background subtraction should be possible. Experiments of this type are now in progress.

We thank the US Office of Naval Research for support of this work under contract no. N00014-77-G-0006.

## TiO<sub>2</sub> on and around a deactivated hydrodesulphurization catalyst

L. E. Makovsky, S. S. Pollack\* & F. R. Brown

US Department of Energy, Pittsburgh Energy Technology Center, PO Box 10940, Pittsburgh, Pennsylvania 15236

Deactivation of catalysts used to promote the liquefaction and desulphurization of coal is usually attributed to structural changes in the catalyst and the buildup of carbonaceous materials, minerals, iron and titanium. We discuss here the nature of the titanium which, though it is one of the major metals to deposit on and around catalysts, has never been characterized. The titanium deposited around a used catalyst removed from a fixed-bed reactor is very similar to one of the TiO<sub>2</sub> polymorphs (anatase) except that the *c* axis is 0.054 Å shorter. Two possible explanations for the origin of the anatase-like material are (1) that the titanium was originally organically bound in the coal, but it became oxidized during coal liquefaction, or (2) that small crystallites of the oxide existed in the coal and were simply concerned on and around the catalyst during liquefaction.

The need for clean fuel sources has led to the development of new processes for the liquefaction of coal. Some, such as the solvent refined coal (SRC) processes, do not use a catalyst, apart from the effects produced by the mineral matter in the feed coal. Others, such as the H-coal process, use an added catalyst, typically Mo promoted with Co or Ni supported on high surface area aluminas. Present usage requires ~1 lb of catalyst with 10% Mo as metal to hydrodesulphurize 1 ton of coal and produce three barrels of liquid fuels; thus it would take ~10 × 10<sup>6</sup> lb of Mo per year to produce one million barrels of liquid per day. (A production of approximately this amount would be required for a catalytic process to influence significantly the generation of liquid fuels in the US.) Because US production of Mo was estimated at 65 × 10<sup>6</sup> lb in 1978 and world production was 194 × 10<sup>6</sup> lb the need for lifetime maximization for Mo-based catalysts is obvious<sup>1</sup>.

Catalyst deactivation has been extensively studied for both petroleum and coal hydrodesulphurization catalysts<sup>2-4</sup>, but the nature of the titanium in the latter was not determined.

Much work at the Pittsburgh Energy Technology Center (PETC) has been devoted to a study of deactivated catalysts (supported Co-Mo on alumina) removed from the SYNTHOIL (fixed-bed) reactor. After 300 h of operation at 450 °C, 4,000 p.s.i., and exposure to 1.3 tons of Homestead, Kentucky coal, the 11 lb of Mo catalyst had become deactivated, as shown by the increase in sulphur content of the liquid product from 0.25 to 0.75%, the latter value equivalent to that found in non-catalytic operations<sup>5</sup>. The studies at PETC have shown that part of the catalyst deactivation may be due to the growth of the MoS<sub>2</sub> crystallites from single layers into three-dimensional stacks containing nine layers<sup>6</sup>. The work reported here is limited to the nature of the titanium deposits found on and around the spent catalyst.

The titanium found in the catalyst is concentrated in the outer 150 μm of the 1/8-inch catalyst pellets and is difficult to separate from the rest of the catalyst. However, surrounding the pellets in the reactor is a greyish deposit similar in composition to the spent catalyst except for lower Al, Mo, and Co contents. (The unused catalyst contains 3% CoO, 15% MoO<sub>3</sub> and 5% SiO<sub>2</sub> on eta Al<sub>2</sub>O<sub>3</sub>.) An X-ray diffraction pattern of this deposit, which contains ~20% Ti, is shown in Fig. 1 *b*. The anatase form of TiO<sub>2</sub>, with lines slightly shifted, is the major crystalline compound in the sample. Calcite, gypsum and quartz which occur in the original coal and pyrrhotite which forms during liquefaction are also present. The strongest line of anatase at 3.52 Å can easily be seen on diffraction patterns of the whole unground pellets, but long counting times are needed to reveal the second-strongest line at 1.89 Å.

The composition of the reactor deposit (shown in Fig. 1) is listed in Table 1. For comparison the analysis of used catalyst from the same portion of the reactor, the outlet side, is also shown.

After treatment with HCl and HF, all but ~15% of the reactor deposit dissolves. (Although Vorres and Donohue<sup>7</sup> showed in 1955 that TiO<sub>2</sub> reacts with HF to form TiOF<sub>2</sub>, this information does not yet seem widely disseminated.) The acid-insoluble residue contains a coke-like material, MoS<sub>2</sub>, and an unidentified magnetite-type spinel (see Fig. 1*a*). From X-ray diffraction linewidth measurements, corrected for instrumental broadening, the crystallite size of the anatase-like material in the reactor deposit was estimated<sup>8</sup> to be in the range 190-260 Å. The positions of the peaks, except the (200), are shifted to

**Table 1** Selected metals, *C* and *H* content of reactor deposit and used catalyst pellets from outlet section of SYNTHOIL reactor

| Element | Reactor deposit % | Used catalyst pellets % |
|---------|-------------------|-------------------------|
| Ti      | 24.5              | 2.9                     |
| Fe      | 7.82              | 0.5                     |
| Al      | 7.81              | 30.1                    |
| Ca      | 1.74              | 0.3                     |
| Mo      | 1.92              | 7.8                     |
| Co      | 0.55              | 1.2                     |
| C       | 15.3              | 9.8                     |
| H       | 1.3               | 0.9                     |

slightly higher angles, and from measurement of six peaks, a *c* axis of 9.460 Å with a standard deviation of 0.006 Å has been calculated using Appleman's<sup>9</sup> least-squares program. This indicates a decrease of 0.054 Å from that measured by Swanson *et al.*<sup>10</sup> for pure anatase. No change in the *a* axis was detected. The reason for the slightly shorter *c* axis of the anatase-like material in the reactor deposit is not known. This material also contains ~1% boron, but when treated with HCl, the boron is found in the soluble fraction, whereas the titanium-rich material is insoluble. Scanning transmission electron microscopy (STEM) studies showed no element other than Ti in the anatase-like crystallites from the reactor deposit. Attempts have been made to study by STEM the TiO<sub>2</sub> on and in the pellets but the preparation of TiO<sub>2</sub> crystallites thin enough to produce electron diffraction patterns has not been achieved.

A sample of the raw coal (Homestead, Kentucky) was treated to concentrate any TiO<sub>2</sub> minerals present. The coal was first ashed at low temperature and then fractionated using bromoform. HCl and HNO<sub>3</sub> were then used to remove calcite and pyrite from the residue. No titanium minerals were detected in the residue even though the coal contains ~0.1% titanium. Quantitative estimates of the inorganic titanium in the Homestead coal have not been made, but Finkelman<sup>11</sup>, using a novel procedure based on SEM and energy-dispersive X-ray fluorescence, has attempted to do this for a Waynesburg coal. He found that approximately half the titanium is in minerals >2 µm in diameter, and the remainder of the titanium is either organically bound or in smaller crystals. The presence of 200-Å anatase crystallites in the Homestead coal is possible because Lin *et al.*<sup>12</sup> have found mineral crystallites 40–1,000 Å in an Illinois no. 6 coal, although they did not specifically find anatase.

Recent work here at PETC has shown that titanium bound as the cresylate, nonylate, or tetraphenyl porphine, when mixed with catalyst, penetrated several hundred micrometres into the pellets. After treatment in an autoclave at 450° and 2,000 p.s.i. hydrogen for 30 min, the titanium in between the pellets had been converted to 600–800-Å anatase crystallites with normal *a* and *c* axes, and the structure of the titanium inside the pellets is under investigation. This work shows that organically bound titanium will form anatase in liquefaction conditions. However, until more conclusive studies rule out the presence of small crystallites of TiO<sub>2</sub> in the original coal, the inorganic origin remains a possibility. Scanning transmission electron microscopy studies and additional differential solubility experiments to concentrate any inorganic TiO<sub>2</sub> present in the raw Homestead coal are in progress. Hopefully, this information will permit resolution of the origin of titanium deposits on at least one coal hydrodesulphurization catalyst.

We thank George Noles at Sandia laboratories for the scanning transmission electron microscopy of the TiO<sub>2</sub> crystallites from the reactor deposit.

## Olivine glass and spinel formed in a laser heated, diamond-anvil high pressure cell

A. Lacam, M. Madon & J. P. Poirier

Institut de Physique du Globe, Université Paris VI, 4 Place Jussieu, 75230 Paris Cedex 05, France

Laser-heated, diamond anvil cells have produced a major breakthrough in the understanding of the physics of the Earth's interior, by making it possible to synthesize mineral phases that are stable at very high pressure. The synthesized phases are usually identified by X-ray powder diffraction techniques. We report here the results of the first local examination by transmission electron microscopy of a sample prepared by heating fayalite in a diamond-anvil cell. We have identified three phases produced, in the pressure gradient from the edge to the centre of the cell: olivine glass (to our knowledge, the first case to be reported); phases corresponding to a transition zone between olivine and spinel; and spinel. The phases are similar to those found in shocked chondritic meteorites.

**Fig. 1** *a*, Scheme of a sample recovered from the diamond-anvil cell and ion-beam thinned. The edges of the hole are transparent to the electrons. *b*, Location of the different zones of the sample in the phase diagram after Ohtani. Zone 1, glass quenched from the melt at lower pressure near the rim. Zone 2, transition zone. Zone 3, γ-spinel at higher pressures near the centre.

Fayalite  $\text{Fe}_2\text{SiO}_4$  is the iron end member of the ferro-magnesian olivine series, which constitute most of the Earth's upper mantle, and whose transition to spinel structure under high pressure has important geodynamic consequences. Pure, single crystalline, synthetic fayalite prepared by zone-melting<sup>3</sup>, was ground in an agate mortar; the powder, consisting mostly of grains  $\sim 3 \mu\text{m}$  in size with a few larger ones ( $\approx 30 \mu\text{m}$ ), was loaded between the diamonds, without a gasket, as a disk 0.8 mm in diameter. Pressure was applied for 2 days before heating. The maximum pressure, measured by the shift of ruby fluorescence lines, was  $109 \pm 10$  kbar in the centre of the specimen and was found to be the same when measured before and after heating. The distribution of pressure across the cell was not measured but the absence of a gasket meant that the pressure at the edge would be close to atmospheric pressure. The beam of a 60-W YAG laser was focused on the sample and scanned across it. The powder density was of the order of  $1 \text{ MW cm}^{-2}$  and the luminance temperature was estimated to be  $1,450^\circ\text{C} \pm 50^\circ\text{C}$  by optical pyrometry. The sample was then recovered and ion-beam thinned until a hole appeared. The elongate hole extended from the centre of the sample to the edge of the transformed zone (Fig. 1). Its edges were thin enough to be examined by transmission electron microscopy in a 100-keV Philips EM300 microscope. From the rim to the centre three structurally different zones were distinguished and could be interpreted in the light of Ohtani's recent phase diagram for melting of  $\text{Fe}_2\text{SiO}_4$  under pressure<sup>4</sup> (Fig. 2). These results were reproduced in two experiments with nominally the same conditions. (In one experiment the recovered sample broke but fragments could be thinned and examined, they yielded the same results).

Fig. 2 Fayalite glass with small fayalite crystals in zone 1.

Zone 1, close to the rim, consists mostly of a material which was totally nondiffracting, melted easily when heated in the beam by removing the condenser apertures of the microscope (this prevented X-ray microanalysis), and contained a few idiomorphic micro crystals of a size much too small ( $< 1,000 \text{ \AA}$ ) to allow characterization by electron diffraction. These three features together with the fact that the pressure at the rim is low enough for fayalite to melt under the impact of the laser beam lead us to believe that we have observed olivine glass quenched from the melt. We believe that this is the first report of an olivine glass quenched from the melt, the only glass previously reported having been produced in the solid state during shock experiments<sup>5</sup>. The highly conducting diamonds can evacuate heat from the very thin layer of melt, fast enough to obtain very high quenching rates comparable with rates ( $\approx 10^6^\circ\text{C s}^{-1}$ ) obtained in the preparation of metallic glasses<sup>6</sup>. We can get an idea of the quenching rate by a rough calculation assuming that a quantity of heat  $Q = 2\lambda\rho cT_0$  per unit area is released instantaneously at

Fig. 3  $\gamma$ -spinel and olivine intergrowths in the transition zone 2. The plane of the foil can be indexed as (010) in olivine or (112) in spinel, the boundaries between the areas in and out of contrast are (100) planes in olivine or ( $\bar{1}\bar{1}\bar{1}$ ) planes in spinel.

time  $t = 0$  in a thin layer of thickness  $2\lambda$  at  $x = 0$  (the sample) and evacuated on both sides by conduction in semi-infinite diamond anvils along the  $x$  axis. If we assume that  $\rho c$  (density  $\times$  heat capacity) is not very different in the thin sample and in the diamonds; the temperature  $T$  at time  $t$  and  $x = 0$  (the temperature of the sample) is given<sup>7</sup> by:  $T = T_0\lambda/(\pi\kappa t)^{1/2}$  where  $\lambda \approx 10^{-3} \text{ cm}$  and  $\kappa$  is the thermal diffusivity of diamond,  $\kappa \approx 1 \text{ cm}^2 \text{ s}^{-1}$ ,  $T_0$  is the temperature of the liquid  $T_0 \approx 1,500^\circ\text{C}$  (the temperature of the diamonds at  $t = 0$  is taken as  $0^\circ\text{C}$ ). We see that for  $t = 10^{-6} \text{ s}$ ,  $T$  falls to  $\sim 850^\circ\text{C}$ , well below the freezing point: the quenching rate is probably higher than  $10^6^\circ\text{C s}^{-1}$ .

Zone 2, inwards of zone 1, probably corresponds to the vicinity of the triple point liquid-fayalite- $\gamma$ -spinel, in the solid state region. It seems to be a transition zone between the olivine and spinel structure, where the electron diffraction patterns can be indexed both as (010) plane in olivine and (112) plane in spinel (Fig. 4). If various spots are used to form the image, different tabular regions of the grains are seen in contrast, the boundaries between these regions lie on (100) plane in olivine or (111) plane in spinel. This structure could be interpreted as corresponding to conditions close to the olivine-spinel boundary in the phase diagram, and is compatible with a model recently proposed<sup>8</sup>, of a martensitic olivine-spinel transition effected by the motion of dissociated [001] dislocations on the (100) close packed planes of olivine, with accompanying synchroshear of the cations.

Zone 3, close to the central region, consists only of  $\gamma$ -spinel. Further from the centre the grains are quite small,  $1 \mu\text{m}$  in diameter, with a polygonal shape; they contain planar defects (stacking faults or antiphase boundaries) (Fig. 4) on (110) planes

Fig. 4  $\gamma$ -spinel with antiphase boundaries in zone 3.

with displacement vector  $1/4[110]$ , identical to the defects previously identified in the ringwoodite of the meteorite Tenham<sup>9-11</sup>. Closer to the centre, the grains become larger (several micrometres), planar defects are no longer visible but numerous straight dislocations aligned along  $\langle 110 \rangle$  directions are present.

In conclusion, transmission electron microscopy has shown that processes taking place in fayalite inside a laser-heated diamond-anvil cell are rather complex and range from melting and olivine glass formation during rapid quench to solid state transition to spinel. Note that the observed phases: glass with small idiomorphic crystals and mosaic spinel polycrystal with antiphase boundaries are very similar to those found in shocked hypersthene chondrites.

We thank Dr H. Takei for the fayalite and C. Guillemin for help with the electron microscopy. This work was supported by INAG (ATP Geodynamique 1979). Contribution IPG NS 417.

## Phytoplankton patchiness indicates the fluctuation spectrum of mesoscale oceanic structure

J. F. R. Gower\*, K. L. Denman\* & R. J. Holyer†

\* Institute of Ocean Sciences, PO Box 6000, Sidney, British Columbia, Canada V8L 4B2

Satellite imagery and large-scale oceanic experiments have replaced traditional concepts of broad sluggish currents moving throughout the ocean by the concept of a continuous distribution of more energetic eddies, the dominant eddies having space scales<sup>1,2</sup> of the order of 100 km. Near the ocean boundaries in such areas as the Gulf Stream and the California Current, these eddies exhibit strong thermal contrast, of the order of 2-6°C, and their structure and distribution can be mapped using satellite thermal IR imagery<sup>3,4</sup>. Over most of the ocean, however, the thermal contrasts are much lower, of the order of 0.1-0.5°C, and tend to be masked from satellite observation by small-scale atmospheric variations. To map the structure associated with mesoscale horizontal water motions in these areas, another indicator must be used for observation from space. We present here the first results of spectral analysis of satellite imagery of what we believe is phytoplankton patchiness controlled by mesoscale (10-100 km) water motions.

The surface layer of the ocean is inhabited by organisms ranging in scale from plankton (~1 µm) to whales (~10 m). Whereas whales often migrate over hemispheric distances, phytoplankton, the microscopic plants in the ocean, have the least mobility, limited to vertical migration over a few metres per day<sup>5</sup> accomplished by buoyancy changes. The phytoplankton may, therefore, be considered as a passive scalar being advected about by the variable ocean currents. Phytoplankton do, however, grow and reproduce; a healthy population can double its biomass in a time period of the order of 1 day<sup>6</sup>. Several

models have been developed to describe growing phytoplankton patches being redistributed and diffused horizontally by a partially turbulent ocean<sup>7-9</sup>. These models have tried to describe the observed spatial variations of biomass in terms of wavenumber spectra. It has recently been concluded<sup>7,8,10</sup> that shipborne sampling cannot achieve sufficient spatial coverage in times short enough to be considered synoptic and that airborne or satellite sampling is required.

The biomass of phytoplankton is usually quantified by determining the amount of chlorophyll *a* pigment present. Remote measurement of chlorophyll concentration uses the colour changes caused by the combination of absorption or fluorescence of chlorophyll pigments and backscattering by associated suspended matter<sup>11-15</sup>. Variations in phytoplankton concentration cause measurable changes in the intensity and spectral distribution of visible light backscattered from the ocean, especially in the blue and green bands where water transmission is a maximum. Normal, low plankton concentrations cause colour changes which can be detected from space only by using specialized processing on selected wavelength bands to remove atmospheric effects. The Coastal Zone Colour Scanner on Nimbus 7 is now available as a sensor designed for this purpose. Areas of high chlorophyll concentration, however, can give large changes in water reflectivity detectable by less sophisticated systems.

Figure 1 shows an area of the ocean 180×250 km in size, south of Iceland, as imaged by the LANDSAT multispectral scanner on 19 June 1976. The image shown is a mosaic of spectral band 4 from frames 2514-12015 and 2514-12021. Band 4 is the shortest wavelength band on the instrument, covering 500-600 nm, corresponding roughly to green light. The south-west coast of Iceland is visible at the top of the image, and the 400-m depth contour crosses the middle of the scene. The land is partly cloud covered and some bands of cloud are visible at the lower right. The island of Westmannaeyjar can be seen just off the coast with the volcanic island, Surtsey, to its south-west. The swirls and eddies in the remaining area of the water show a structure characteristic of mesoscale turbulence as observed in satellite thermal imagery. This structure is much less visible in the red band, while the longest wavelength band 7 (800-1,100 nm) shows only the clouds above featureless dark water. Because this band-spectral signature is typical of suspended matter in the ocean, we interpret the eddy patterns in Fig. 1 as representing the distribution of phytoplankton biomass or of detritus derived from phytoplankton.

A phytoplankton survey tow was made in the area as part of a programme of the Institute for Marine Environmental Research, UK, on the day this image was taken. The ship travelled westwards parallel to the coast ~20-km offshore passing between Westmannaeyjar and Surtsey. The concentration of phytoplankton observed was well below average for the time of year confirming, at least, that the darker area near the top of the image corresponds to a low concentration of phytoplankton. Measurements made along the same line six weeks earlier, however, showed the strongest phytoplankton bloom observed in this area during May for five years. Repeated measurements made on a section to the west of Westmannaeyjar by staff of the Marine Research Institute of Reykjavik<sup>16</sup> showed that the main peak of growth in this area also occurred about a month earlier. Their data for 1976-78 show that the blooms tend to occur earlier in the shallower water on the continental shelf than in the deeper water offshore where the bloom in Fig. 1 is observed. These data also showed that an exceptionally high productivity of phytoplankton occurred in the spring of 1976. The available data, then, confirm strong productivity near this place and time and do not invalidate our interpretation of Fig. 1 as showing the effects of a phytoplankton bloom. The area of the bloom covers at least 180×180 km, the area of a single frame of LANDSAT imagery. The increase in reflectance caused by the bloom is high, but not unreasonable for plankton of the appropriate species<sup>11</sup> or in the appropriate stage of development<sup>17</sup>. No other LANDSAT scenes were collected over the area near this time

except for an image overlapping the area of Fig. 1 but farther east, largely cloud covered, recorded on 30 May. This image shows no discernible bloom. Scarcity of satellite data is largely due to there having been no satellite receiving station capable of receiving directly image data of Iceland.

The characteristic spatial scales of the eddies and ocean turbulence structure can best be determined from a two-dimensional spectral analysis<sup>18</sup> of the image in which we assume that the increase in pixel value over the level for clear water is proportional to phytoplankton concentration. The resulting power spectrum can then be averaged over all directions to get a spectrum as a function of a nondirectional wave number<sup>19</sup>.

**Fig. 1** Enhanced image formed from two LANDSAT Multispectral Scanner band 4 frames showing increased reflectance in the Atlantic Ocean south of Iceland on 19 June 1976. The patterns are interpreted as due to a plankton bloom in water advected by ocean mesoscale turbulence.

Before beginning this analysis, the effects of cloud were reduced by subtracting the band 7 image, suitably scaled, from the band 4 image. As water looks very dark in band 7 (near IR), the subtraction is equivalent to removing the light backscattered by aerosol particles in thin clouds and haze above the water. This scaling allows for the different instrument gain and solar irradiance between bands 4 and 7 and also, in effect, selects different values of mean Angstrom coefficient for the spectral dependence of aerosol scattering in the scene<sup>20</sup>. The scaling constant was adjusted to reduce the visibility of cloud features in the band 4 image. In ~10% of the area of Fig. 1 analysed, thin cloud contributed an additional 15–30% to the radiance enhancement in band 4 that is due to light scatterers in the water. The subtraction reduced this cloud contribution to ~5%. Less correction is possible in areas with thicker cloud, but these were largely avoided in the analysis.

Picture elements in the raw image are spaced on a grid with element spacing  $57 \times 79$  m. The pixel values were averaged over groups of  $8 \times 6$  pixels to reduce instrument noise and to give a roughly square grid of about 474-m spacing for further processing. Three overlapping areas of  $256 \times 256$  averaged pixels each about 120 km square were then selected for Fourier transforming. The mean pixel value for each was subtracted from each pixel in the area, and the areas were Hanned (weighted with a cosine taper in both dimensions) to reduce edge effects.

Although the three areas overlapped by ~55%, the Hanning reduced the correlation of the coefficients of the resulting transforms to ~25%, low enough for reasonable statistical independence. The Fourier transforms of the pixel arrays were then converted to power or signal-variance spectra, and circular ring areas in the transform plane were summed and normalized by their areas to give non-directional estimates of the variance as a function of wavelength. Wedge-shaped areas were similarly summed to give estimates of the directional effects in the water or introduced by residual cloud signals. These were found to be <10% except at the shortest wavelengths (<3 km) where a larger value (up to 20%) appears in the direction range appropriate to the cloud streaks in Fig. 1.

The logarithms of the spectral components of signal variance, averaged over all directions, are plotted in Fig. 2 against the logarithm of the inverse wavelength,  $K$ . If the spectral components are dependent on  $K$  in a power law manner, proportional to  $K^n$ , then such a plot should yield a straight line with slope  $n$ . The spectral components computed for the three areas are plotted separately and all yield a similar relation for the wavelength range 2–60 km ( $K = 0.015$  to  $0.5$ ); the relations can be well fitted by straight lines. The regression line slopes are  $-3.11$ ,  $-2.83$  and  $-2.82$  for the three areas giving an average value of  $-2.92$ . The average regression line is plotted as the dashed line in Fig. 2. At long wavelengths, the points lie below this line, but some roll off is expected for components having wavelengths comparable to the dimensions of the sample area. The point for a wavelength of 1 km lies above the line indicating reduction in slope at the short wavelength. This value may be increased by components of scene radiance due to residual cloud reflections. Variance due to small streaks of cloud such as can be seen in Fig. 1 would be expected to have more energy at the higher frequencies.

For wavelengths between 2 and 60 km the distribution of signal variance is related to inverse wavelength to the power  $-2.9$ . If the observed pixel values are interpreted as proportional to particulate backscatter from phytoplankton, then this power law also applies to the phytoplankton density and the above result can be compared with other measurements of the power law index in ocean mesoscale turbulence.

Spectra of sea-surface temperatures derived from airborne radiometer measurements have varied between  $-2$  and  $-3$  (refs 18, 19). Shipboard estimates of phytoplankton patchiness have varied widely, but a similar range is most typical<sup>10,21–23</sup>. Theoretical estimates<sup>7–9</sup> of the index for turbulence-controlled phytoplankton patchiness tend to be between  $-2$  and  $-3$ . The  $-3$  slope is consistent with the concept of two-dimensional geostrophical turbulence<sup>24,25</sup>, where the growth rate of the phytoplankton has a negligible effect on the horizontal distribution of biomass. The signal discontinuities resulting from the small (~10) number of discrete pixel values or grey scale levels in the original image would shift the slope towards  $-2$  (ref. 26), but this effect is reduced to a negligible amount by averaging over 48 pixels.

The relationship between phytoplankton concentration and the amount of radiance upwelling from beneath the sea surface is not in general linear. The absorption by chlorophyllous pigment increases along with the increased backscatter from the suspended planktonic matter<sup>12,13</sup>. In the range 500–600 nm, this leads to saturation in the reflectance values after an initial increase. Over a limited range of chlorophyll concentrations, however, the relationship can be approximated by a linear function so that the above discussion holds. The reflectance values in the areas analysed range over ~3–7% reflectance. The expected linearity of the reflectance-to-chlorophyll relation depends on the properties of the plankton actually present. The relatively high reflectivity of the water implies a high backscatter to absorption ratio, a condition which improves the linearity of the relationship.

We interpret patterns on a LANDSAT band 4 multispectral scanner image as being due to phytoplankton and show that the fluctuation spectrum is consistent with the phytoplankton dis-

**Fig. 2** Power spectra computed from three overlapping areas of Fig. 1 as described in the text. A slope of  $-3$  in a log-log plot is characteristic of turbulent motion, and indicates that growth rate of the plankton itself is having a relatively small effect. The distribution of enhanced water reflectance in Fig. 1 should, therefore, be a useful tracer of the eddy motions.

tribution being controlled by advection in variable ocean currents, while being unaffected by their reproduction rate.

The phytoplankton are, therefore, behaving as a passive scalar and the distribution of enhanced water reflectance in Fig. 1 can be used as a tracer of eddy motion. The spatial distribution of areas showing increased reflectance can certainly be mapped more precisely from a satellite than by any other means available, and this may be why the resulting slope of the power spectrum agrees so well with theory. The problem of relating this reflectance increase to exact measures of chlorophyll concentration remains, but this should soon be possible using the improved data from NASA's Coastal Zone Colour Scanner.

In comparing satellite IR and colour mapping of ocean eddy structure both have their limitations, and the two methods will to some extent be complementary. Both methods are blocked by clouds, and both are affected by atmospheric absorption and scattering. Both measure only surface phenomena, though wind mixing, particularly at high latitudes, will tend to average properties over a surface mixed layer, often of the order of 50 m deep. Thermal measurements are more susceptible to skin effects related to the very small penetration depth ( $\leq 0.1$  mm) of thermal radiation. Both measurements are of ocean properties interesting and important in themselves. Taken together they can show how solar heating, water mixing and stratification, and plankton growth lead to the productivity variations that are of such importance to the world's fisheries.

## The nature of inherited deafness in deafness mice

Karen P. Steel & Gregory R. Bock

MRC Institute of Hearing Research, University of Nottingham, Nottingham NG7 2RD, UK

Many mouse mutants have an apparent deficiency in their responsiveness to sound<sup>1</sup>. Most of these mutants have other abnormalities in addition to their hearing deficit, and the only two which have been subjected to a detailed anatomical and physiological study, *shaker-1* and *Ames waltzer*, also have motor abnormalities<sup>2,3</sup>. The existence of such motor abnormalities throws some doubt on the usefulness of these two mutants as possible models for hereditary deafness in man, which is most frequently uncomplicated<sup>4</sup>. Deol and Kocher have described the *deafness* mutation in which mice homozygous for the recessive *deafness* gene (*dn/dn*) were unresponsive to sound and had no significant behavioural abnormality<sup>5</sup>. Cochlear hair cells in *deafness* mice develop normally and then degenerate, and the adult animals are completely deaf<sup>6</sup>. We have now studied *deafness* mice in order to determine the nature of their inherited deafness. Our data indicate that stimulus-related cochlear potentials do not develop even though hair cells are present in the young animal. The endocochlear potential is present in the scala media, but behaves abnormally during anoxia.

*Deafness* mice were bred in our laboratory from stock obtained from M.S. Deol, University College, London. Heterozygotes (*+dn*) were used as controls, and were distinguished from their homozygous (*dn/dn*) littermates by the failure of the latter to exhibit a Preyer reflex in response to a metallic click. Gross VIIIth nerve action potential thresholds for control animals are presented in Fig. 1. No action potentials could be detected in *deafness* mice in any age group at any frequency, even when 5,000 stimulus repetitions were included in the average.

Cochlear microphonics in response to discrete continuous tones between 1 kHz and 60 kHz were recorded from the same electrode and measured with a computer-controlled lock-in amplifier. No cochlear microphonic could be recorded at any age in the mutant mice, although normal microphonics with maximum amplitudes of about 100  $\mu$ V were found in control animals. Resting noise levels for these measurements were below 0.1  $\mu$ V.

After the electrophysiological experiments, the cochleas were removed and fixed in a buffered paraformaldehyde/glutaraldehyde fixative and embedded in Spurr low-viscosity resin. In surface preparations, most of the cochlear hair cells are present and apparently intact in young (13 to 17 day) *dn/dn* mice, but there is a progressive degeneration so that fewer than 15% of the hair cells remain at 40 days. However, 2- $\mu$ m thick sections from young *deafness* mice revealed structural abnormalities in the organ of Corti even at the time when hair cells are still present. In particular, the fluid spaces around the outer hair cells and in the tunnel of Corti do not develop normally. There were no gross abnormalities in the stria vascularis.

Endocochlear potential (the positive d.c. resting potential in the scala media) was examined in mice aged 26–30 days. Potentials were measured and anoxia was induced by sealing the tracheal cannula. The data presented in Fig. 2 show that the resting potentials are identical in control and *deafness* animals, but that *deafness* animals do not show the large negative anoxia potential usually observed in scala media during anoxia<sup>7</sup>.

The present study shows a normal pattern of development in control animals<sup>8</sup>, and suggests that *deafness* mice are profoundly deaf during all stages of cochlear development, including the early stages when most hair cells are intact. There are two possible explanations for the absence of microphonics in *deafness* mice: (1) mechanical stimulation of the hair cells is absent, or (2) the mechanism of generating the microphonic from mechanical stimulation is not functioning. The first possibility seems unlikely because we can detect no external or middle ear abnormalities in the mutants. It is generally assumed that the positive endocochlear potential provides a driving force for potassium ions to cross the apical surfaces of hair cells, and that mechanical stimulation controls the opening of ion channels in the hair cell membrane, thus giving rise to the cochlear microphonic<sup>9,10</sup>. Since the positive endocochlear potential is present in *deafness*, the most likely explanation for the absence of microphonics is that the ion channels are not opening normally. It is not yet clear whether this failure constitutes the primary action of the *deafness* gene, or whether it follows as a consequence of some other genetically determined abnormality.

**Fig. 1** Mean gross VIIIth nerve action potential thresholds (as sound pressure level in dB SPL) recorded from control mice aged 12, 13, 15, 17, and 20 days after birth. Animals were anaesthetized with urethane (1.5 mg per g intraperitoneally), a tracheal cannula was inserted and the gross VIIIth nerve action potentials were recorded from a silver wire electrode on the round window. Action potentials were amplified, digitized, and averaged on a microcomputer. Responses to tone bursts (40-ms duration, 2-ms rise/fall time) delivered through a closed sound system were recorded, and threshold at a given frequency was taken to be 2.5 dB SPL below the lowest intensity producing a detectable response in an average of 50 stimulus repetitions. Six animals were studied in each age group. The broken line shows the peak output of the sound system at various frequencies.

**Fig. 2** Animals were prepared as described for Fig. 1 and a glass microelectrode filled with 3 M potassium acetate was inserted into the scala media through a fenestra over the stria vascularis of the basal turn. The potential was recorded as a function of time after the onset of anoxia induced by sealing the tracheal cannula. Each curve shows mean potentials from six animals, and the vertical bars indicate s.e.m. The insert shows the first 5 min of anoxia on an expanded scale. Mean resting potentials were 109 mV (s.e.m. = 2.6 mV) in control animals (+/dn) and 104 mV (s.e.m. = 3.1 mV) in *deafness* animals (*dn/dn*). Mean minimum anoxia potentials were -35 mV (s.e.m. = 1.4 mV) and -9 mV (s.e.m. = 2.7 mV) respectively. Analysis of variance indicated a significant ( $F = 48$ , d.f. = 1,  $P < 0.001$ ) interaction between genetic constitution and recording condition (resting potential versus anoxia potential).

Recent work on acoustic trauma and ototoxic drug-induced cochlear damage has indicated that an increase in the electrical resistance of the boundaries of the scala media as a result of this damage leads to a decrease in the negativity of the anoxia potential.<sup>11,12</sup> This is consistent with our suggestion that the ion channels across the apical surfaces of the hair cells are not opening correctly, which would lead to an increase in the electrical resistance, and a reduction in the negativity of the anoxia potential, as observed. However, our endocochlear potential data are difficult to reconcile with the generally accepted mechanism of endocochlear potential generation. It is widely assumed that the resting endocochlear potential is the sum of an active positive electrogenic component and a passive negative diffusion potential, the latter being the only component present during anoxia<sup>7,13</sup>. The absence of a large negative diffusion potential in *deafness* mice might be expected to lead to the occurrence of a significantly larger positive resting potential compared with the resting potential in control mice. This is clearly not the case in our data. We are currently measuring potassium concentration in scala media of *deafness* mice in an attempt to resolve this problem.

Finally, we suggest that the *deafness* mutant offers a promising animal model of profound hereditary deafness in man. The mutant can be used to study both the primary action of a mutation giving an uncomplicated form of deafness, and the central consequences of the total absence of auditory input during development.

We thank Dr M. S. Deol for providing mice from the *deafness* stock, Mr A. C. Davis for statistical advice and Drs M. P. Haggard and G. K. Yates for critical comments on the manuscript. This research was carried out within the framework of the European Economic Communities' Concerted Action programme for auditory research.

## Genetically determined susceptibility to *Leishmania tropica* infection is expressed by haematopoietic donor cells in mouse radiation chimaeras

J. G. Howard\*, Christine Hale\* & F. Y. Liew†

\* Division of Experimental Biology and † Department of Experimental Immunobiology, The Wellcome Research Laboratories, Beckenham, Kent BR3 3BS, UK

Models of the different disease patterns of cutaneous leishmaniasis can be established by infecting various inbred strains of mice with *Leishmania tropica*. The BALB/c strain is exceptionally susceptible in that the infection is dosage independent and inexorably progressive, terminating in cutaneous and fatal visceral metastasis<sup>1-3</sup>. This is largely determined by a single autosomal non-H-2-linked gene<sup>3</sup>, seemingly not identical to the well-characterized *Lsh* gene which determines innate susceptibility to systemic *Leishmania donovani* infection<sup>4,5</sup>. Although H-2-linked genetic influences are also detectable in the immune stage of both leishmanial infections<sup>3,6</sup>, they are relatively minor in the case of *L. tropica*. Thus, although progression of disease induced by lower infecting doses is slower in congenic BALB/K (H-2<sup>b</sup>) than in BALB/c or BALB/B (H-2<sup>b</sup>) mice, the eventual outcome is similar in all three<sup>3</sup>. This inability to control *L. tropica* infection seems to involve profound impairment of potentially curative cell-mediated immunity by the generation of a specific suppressor T-cell population<sup>7</sup>. With two other pathogens which infect mononuclear phagocytes, *Listeria monocytogenes* and *Mycobacterium lepraemurium*, differences in mouse strain susceptibility have been attributed to extrinsic factors regulating macrophage activity rather than to intrinsic gene expression within the cells themselves<sup>8,9</sup>. The relative strain susceptibility of mice to myxoviruses (determined by the dominant allele *Mx*) is also a genetic characteristic of their macrophages *in vitro*<sup>10</sup>. Nevertheless, radiation chimaeras exhibit the myxovirus resistance profile of the host despite near-total haematopoietic cell replacement, including donor macrophages which can still express their original susceptibility *in vitro*<sup>11</sup>. In contrast, the experiments described here indicate unequivocally that susceptibility to *L. tropica* in radiation chimaeras compatible at the major histocompatibility (H-2) locus is determined by the descendants of donor haematopoietic cells and not by host environmental factors.

Lethally irradiated mice injected with allogeneic bone marrow cells develop not only haematopoietic and lymphoid cells but also macrophages which are predominantly of donor type<sup>12,13</sup>. When an H-2 incompatibility is involved, mature T lymphocytes must be excluded from the donor cells to avoid the development of fatal graft-versus-host disease<sup>14</sup>. This complication is very rare when untreated marrow is transferred across a non-H-2 incompatibility and the chimaeras survive with extensive replacement of lympho-haematopoietic tissues by donor cells<sup>15</sup>. We have adapted this situation to establish reciprocal chimaerism between two H-2-compatible pairs of strains which differ widely in their susceptibility to *L. tropica*<sup>3</sup>: (1) BALB/B and C57BL/6, respectively highly susceptible and resistant,

both H-2<sup>b</sup>; (2) BALB/c and B10.D2, respectively highly and intermediately susceptible, both H-2<sup>d</sup>.

BALB/B and BALB/c mice were given 800 rads whole body irradiation, C57BL/6 and B10.D2 900 rads at a rate of 50 rads min<sup>-1</sup> from a <sup>137</sup>Cs source. They were injected the same day with  $5 \times 10^6$  bone marrow cells either syngeneic or from the H-2-compatible paired strain. Twelve weeks later they were injected over the shaved rump with  $2 \times 10^7$  viable *L. tropica* promastigotes and the ensuing lesions were observed and measured for 80-100 days as previously described<sup>3</sup> (Figs 1, 2). Syngeneically reconstituted chimaeras behaved indistinguishably from intact untreated members of the same strain. With strain pair (1), lesions in BALB/B grew progressively to fatal termination by 80-110 days, whereas in C57BL/6 they remained small and arrested by 20-30 days, with gradual healing. The same two diverging patterns were presented by the allogeneic chimaeras according to the behaviour of the donor: BALB/B → C57BL/6 highly susceptible, C57BL/6 → BALB/B relatively resistant. Complementary findings were obtained with strain pair (2), although here the differences were smaller, reflecting the lesser resistance of B10.D2 than C57BL/6. In this instance, BALB/c → B10.D2 or BALB/c chimaeras were equally susceptible, whereas B10.D2 → BALB/c or B10.D2 showed a similar intermediate profile.

Fig. 1 The course of *L. tropica* infection in H-2<sup>b</sup>-compatible radiation chimaeras. BALB/B and C57BL/6 male mice were injected subcutaneously over the rump with  $2 \times 10^7$  promastigotes 12 weeks after lethal irradiation and reconstitution at age 8-10 weeks with  $5 \times 10^6$  bone marrow cells from BALB/B (●) or C57BL/6 (○) donors. The mean lesion size  $\pm$  s.e. is represented ( $n=5$ ). (Recipients of BALB/B cells died from disseminated leishmaniasis within 80-110 days.) The susceptibility profiles in both recipient strains are those characteristic of the donor.

These results clearly indicate that the susceptibility to *L. tropica* infection of all four recipient strains studied assumed that of the donor used to establish chimaerism, whether it be more or less resistant. Hence, the exceptional susceptibility of BALB/c and its H-2-congenic derivative lines is expressed intrinsically in some population(s) of haematopoietically derived cells, as this property is transferable by them to a resistant strain. The converse effect implies equally that BALB/c susceptibility is not an environmental influence, in striking contrast with *L. monocytogenes* infection, where reciprocal B10.A and A strain chimaeras have consistently retained resistance characteristic of the host<sup>8</sup>. Similar extrinsic regulation of macrophage activity underlying strain differences in susceptibility to *M. lepraemurium* infection is implicit in recent *in vitro* studies<sup>9</sup>, but this has not been evaluated in chimaeric animals. The fact that radiation chimaeras between strains resistant or susceptible to myxoviruses retain the

**Fig. 2** The course of *L. tropica* infection in H-2<sup>d</sup>-compatible radiation chimaeras. BALB/c and B10.D2 mice were irradiated and reconstituted with BALB/c (●) and B10.D2 (○) bone marrow cells, infected and their lesions followed as in Fig. 1 ( $n = 7$ ). (Recipients of BALB/c cells died from disseminated leishmaniasis within 90–110 days.) As in Fig. 1, the susceptibility profiles again correspond with those of the donor.

characteristic of the recipient, despite replacement of their macrophages by cells displaying donor phenotype *in vitro*<sup>11</sup>, suggests a wider distribution of cell targets for this infection. In the case of avian leukosis virus, however, where the target is the B lymphocyte alone, transference of genetic resistance and susceptibility has been achieved in chickens by post-hatching exchange of semi-allogeneic bursal cells<sup>16</sup>. The conversion of resistance to *Salmonella typhimurium* into donor-type susceptibility has been achieved by establishing bone marrow chimaerism with the C57BL/10→(C57BL/10×A/J)F<sub>1</sub> combination<sup>17</sup>, although the shift from susceptibility to resistance using the converse was detectable only in the early stage of infection and did not persist. The fact that *L. tropica* is an obligate macrophage parasite clearly contributes to the successful conversion of susceptibility into that of the haematopoietic cell donor in the present study. Although our data do not formally establish that the major gene expression is in macrophages rather than suppressor T-cell lineage, this does seem the more likely possibility by analogy with *L. donovani*, towards which isolated Kupffer cells behave *in vitro* as predicted by their strain of origin (J. Blackwell and D. J. Bradley, personal communication).

In conclusion, we report an example in which genetically determined susceptibility to a parasite infection is restricted to haematopoietic cell lineage, such that its replacement by radiation-induced chimaerism is accompanied by acquisition of the resistance/susceptibility phenotype of the donor.

## Recognition of cell types by axonal growth cones *in vitro*

Friedrich Bonhoeffer & Julita Huf

Max-Planck-Institut für Virusforschung, Abteilung Physikalische Biologie, Tübingen, FRG

One of the most intriguing problems in neuroembryology is that of how growing axons find the correct way to their proper target cells. Several pathfinding mechanisms have been envisaged, including mechanical guidance through channels, guidance by diffusible substances and guidance by non-diffusible chemical cues expressed on cell surfaces and sensed by axonal growth cones. Here we describe experiments in which axons growing out from retinal explants are given the choice between two cell monolayers consisting of either retinal or tectal cells and we find that they grow preferentially over the surface covered with tectal cells. This preferential adhesion between retinal growth cones and cells originating from the *in vivo* target seems to be a property specific to the growth cone. In contrast, sorting experiments indicate that the perikarya of retinal cells adhere preferentially to retinal rather than tectal cells. It is likely that this adhesive property is due to recognition of cues expressed on the cell surfaces.

The experimental design is shown in Fig. 1. Axons originating from explants of chick retina grow through a zone where they are simultaneously exposed to two different cell types (retinal and tectal cells) and where they may 'choose' the more attractive one. A retinal explant is spread on a black membrane filter with the layer containing the ganglion cells facing up. The explant is stained with a fluorescent dye and placed upside down on the cell monolayer I. In growth medium, fluorescent axons grow from the explant towards a glass rod coated with monolayer II. Axons reaching the second monolayer have the choice between two cell types: either they decide to grow along monolayer I (Fig. 1, axon a) or along monolayer II (Fig. 1, axon b). This decision reveals their preference for a certain cell type. The ratio of fibres growing upwards along monolayer II and therefore out of the focal plane of monolayer I to that of the fibres which stay in that focal plane reflects the preference of the growth cones for the cell type of monolayer II.

To follow living axons growing in tissue or on a monolayer of cells, we have developed a technique using rhodamine-isothiocyanate (RITC) as a vital stain. Retinal explants stained with RITC and subsequently washed produce axons which remain well stained over 2 days. Figure 2 shows outgrowing fibres on an unstained monolayer of retinal cells. Outgrowing axons tend to keep their original direction over a long distance. The original direction of the fibres leaving the explant corresponds closely with the orientation of axonal growth within the retina *in vivo* where the axons are growing towards the optic fissure.

In control experiments both monolayers I and II consist of the same cell type. Our expectation is that half the axons reaching monolayer II on the glass rod should grow along monolayer I and the other half along monolayer II. However, as demonstrated in Table 1, only about 30% grow along monolayer II.

**Table 1** Fraction of fibres growing along monolayer II

| Monolayer I derived from | Monolayer II derived from |                 |                     |
|--------------------------|---------------------------|-----------------|---------------------|
|                          | Retinal cells             | Tectal cells    | Telencephalic cells |
| Retinal cells            | 0.31 (158/352)            | 0.72 (1075/417) | 0.39 (79/124)       |
| Tectal cells             | 0.036 (63/1687)           | 0.34 (289/565)  | 0.16 (94/480)       |
| Telencephalic cells      | 0.35 (46/86)              | 0.75 (130/43)   | —                   |

The total number of axons counted is shown in parentheses. The first number refers to axons growing along monolayer II, the second number refers to those which grow along monolayer I.

**Fig. 1** Principle of experimental arrangement. The retina of a 6-day-old chick embryo was surgically isolated. A black membrane filter (Sartorius, SM 13006,  $0.45\ \mu\text{m}$  pores) was soaked in Ca-Mg-free Hank's solution containing Con A ( $0.1\ \text{mg ml}^{-1}$ ) for 1 h and subsequently washed with the same buffer. The retina was spread on the membrane filter in Ca-Mg-free Hank's solution. The membrane filter containing the retina preparation was placed briefly on a dry filter paper; thus, the retina becomes firmly attached to the membrane filter. This was then placed into a staining solution, prepared as follows: 1 mg of RITC is dissolved in  $20\ \mu\text{l}$  dimethyl sulphoxide; this solution is diluted 1:5,000 with vigorous shaking into Ca-Mg-free Hank's solution. After 15 min of incubation in staining solution at room temperature, the retina and the supporting membrane filter were washed three times with Hank's solution and then incubated in culture medium (Eagle's medium containing 10% calf serum and 2% chicken serum) for 1 h at  $37^\circ\text{C}$ . Then the supporting filter with the retina was again briefly placed on a filter paper to remove the liquid and chopped into strips  $0.3\ \text{mm}$  wide. These strips were placed on the monolayer as indicated in the figure. The layer of ganglion cells touches the monolayer. The strips were held in position by small stainless steel weights at the ends of the strips where they were not covered by retina. The monolayers were prepared as follows: retina, tectum or telencephalon of chick embryos was prepared and incubated for 10 min at room temperature and for another 10 min at  $37^\circ\text{C}$  in Hank's solution containing  $1\text{--}2\ \text{mg ml}^{-1}$  trypsin. The tissue was then thoroughly washed, taken up in culture medium containing  $25\ \mu\text{g ml}^{-1}$  DNase I at a concentration corresponding to  $2\text{--}5 \times 10^6$  cells per ml, incubated for 5 min at  $37^\circ\text{C}$  and carefully dispersed by forcing the tissue twice through a capillary (10 cm long,  $0.4\ \text{mm}$  in diameter). This cell suspension was diluted with an equal volume of Ca-Mg-free Hank's solution and centrifuged for 10 min at 600 r.p.m. and  $4^\circ\text{C}$ . The sediment was taken up in Hank's solution at a concentration of  $3 \times 10^7$  cells per ml. About  $0.25\ \text{ml}$  of the cell suspension was placed on top of a pretreated coverslip ( $20\ \text{mm}$  in diameter) and the cells were allowed to settle at room temperature. After 15 min the coverslip was carefully rinsed with culture medium and kept in culture medium at  $37^\circ\text{C}$  until used for the experiment. The monolayers on the glass rods were prepared correspondingly. Pretreatment of coverslips and glass rods was necessary to achieve good cell adhesion. The silan treatment was done according to a method described by Gottlieb<sup>6</sup>. Before being used for production of monolayers, the derivatized glass was cleaned by wiping with cotton, then incubated in a Con A solution ( $1\ \text{mg ml}^{-1}$  Con A in Hank's solution) at room temperature for 1 h and finally rinsed in Hank's solution. Microscopic observation was done at  $\sim 24\ \text{h}$  after explantation, as described in Fig. 2 legend. Whether an axon is rising or staying on monolayer I was determined for each axon by changing the focal plane of observation.

It should be mentioned that the monolayers are contiguous, that the axons grow exclusively on cell monolayers and that they are completely unable to use pretreated glass covered with concanavalin A (Con A) as a substratum. At the interface of monolayer I and II, neither branching nor growing back on monolayer II has been observed.

It would be interesting to know whether axons arising from a certain position within the retina show a preference for tectal cells from a corresponding tectal area in this *in vitro* system. Experiments on antero-posterior positional effects are in progress.

Our experiments show that the growth cones of retinal axons have a clear preference for tectal cells. Is this preference a general surface property of retinal cells or is it specific to their outgrowing axons? This question can be answered by sorting experiments of the kind extensively used by Moscona<sup>1</sup>. Single-cell suspensions of retinal and tectal cells are mixed and allowed to form aggregates. If these aggregates are incubated for 24 h the cells sort out in such a way that the core preferentially

**Fig. 2** Fluorescent retinal axons growing on a monolayer of retinal cells. The edge of the stained explant is at the left. Staining of explant and preparation of monolayer are described in Fig. 1 legend. The microscopic observation is done with epifluorescence at a wavelength  $>590\ \text{nm}$  in an inverted Zeiss microscope with an image-intensifying TV camera (Siemens). The incident light range is  $510\text{--}560\ \text{nm}$ . With this technique the axons can easily be detected on a monolayer of cells.

The tendency of axons to remain on the coverslip monolayer may reflect a tendency to grow in straight rather than curved paths, or incomplete contact between the monolayers.

In test experiments, one of the monolayers was prepared from retinal cells, the other from tectal cells. In all experiments retinal axons show a strong preference for cells derived from the tectum, their *in vivo* target. The preference is more pronounced if monolayer I contains tectal cells (Table 1). In 15 separate experiments, 72% of a total of 1,492 fibres preferred tectal cells on the glass rod to retinal cells on the coverslip, whereas only 4% of 1,416 fibres grew to the glass rod when it was covered with retinal cells and the coverslip contained the tectal cells. There are slight variations between experiments but in all 15 in which the glass rod carried the tectal cells, appreciably more than 50% of the axons grew along the glass rod; in none of the experiments with tectal cells on the coverslip did more than 10% of the axons grow along the glass rod carrying retinal cells. Telencephalon monolayers are no more attractive for retinal axons than retinal monolayers, and much less attractive than tectal monolayers (Table 1).

contains retinal cells, whereas the periphery consists preferentially of cells derived from the tectum. This sorting out can be observed in a fluorescence microscope if, for example, the retinal and tectal cells have been stained before mixing with RITC and fluorescein isothiocyanate (FITC), respectively. Pictures of two typical aggregates after sorting are shown in Fig. 3. The fluorescence of tectal cells is seen in Fig. 3a, that of retinal cells in Fig. 3b. Black-and-white pictures of the whole aggregates taken in one plane of focus inadequately demonstrate the clear sorting out of the two cell types, whereas direct observation of the stained cells in various focal planes show sorting out very clearly. In experiments with tectal and retinal cells derived from embryos of various ages (6, 7, 9 days), retinal cells are always in the centre of the aggregates and tectal cells always in the outer shell. According to Steinberg<sup>2</sup>, sorting experiments of this kind reveal a hierarchy of cell adhesiveness; those cells in the middle adhere more tightly to each other than to the cells of the outer shell. This indicates that for cell perikarya retina-retina adhesion is stronger than retina-tectum adhesion, in contrast to the adhesion of the retinal growth cones which, in spite of their retinal origin, adhere preferentially to tectal cells.

The combination of axon choice and cell-sorting experiments suggests that growth cones have adhesive properties which differ from the adhesive properties of the perikarya from which they

**Fig. 3** Sorting out of tectal and retinal cells. Tectal and retinal cells were labelled with RITC and FITC, respectively, as described by Burt and Gierer<sup>5</sup>, and taken up in Eagle's medium containing 20% calf serum, mixed at a concentration of about  $10^7$  cells  $\text{ml}^{-1}$  for each cell type. They were incubated on a gyratory shaker in an Erlenmeyer flask (25 ml) with 60 r.p.m. at 37 °C for 18–30 h. *a*, Fluorescence of tectal cells was observed at wavelengths  $>590$  nm with an illumination at 546 nm. *b*, Fluorescence of retinal cells was observed at wavelengths of 520–560 nm with an illumination of 450–490 nm.

originate. However, remember that sorting experiments are concerned with a mixture of all types of retinal and tectal cells and not with a pure population of retinal ganglion cells—probably the only origin of all fibres observed—and tectal target cells.

It has long been known that axonal growth is very dependent on the material offered as substratum (see, for example, ref. 3). Our experiments show that the growth cones of retinal cells can discriminate *in vitro* between various neural cell types and this capability may be used for *in vitro* axonal guidance. It remains to be shown that the guidance of axons *in vitro* corresponds with the axonal guidance in a developing brain. We believe that the present experiments strongly support the idea that growth of axons along specific pathways *in vivo* may be mediated by characteristic affinities of growth cones for specific cell surfaces. The system we describe lends itself to biochemical analysis of the specific recognition of cell types by growth cones.

We thank Dr Alfred Gierer and Michael Claviez for stimulating discussions, and Alfred Schöffski for help with the sorting experiments.

## Cross-reactivity for different type A influenza viruses of a cloned T-killer cell line

Lin Yun Lu & Brigitte A. Askonas\*

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

Spleen cytotoxic T cells killing influenza virus-infected target cells are cross-reactive for the different type A influenza viruses, in contrast to the circulating antibodies, which show fine specificity for each A virus subtype variant<sup>1,2</sup>. This finding has raised the question of whether a single T cell can recognize cells infected with all the type A viruses. T-killer cell lines with specificity for alloantigens and the male Y antigen can be selected by means of growth factors present in the supernatant of T cells stimulated with concanavalin A (refs 3–7). We report here that we have been able to establish clones of mouse T cells killing target cells infected with influenza virus. Our cell line maintains the same specificity as the heterogeneous spleen cell population from infected mice, in as far as the T-killer cells are specific for A influenza virus, but do not discriminate between the different type A viruses. The cell line maintains H-2 restriction and does not kill cells infected with B influenza virus. The cells grow in the presence of T-cell growth factor and do not require antigen for growth although they maintain their receptors for type A virus. They can also be stimulated by irradiated T-helper cells from mice primed by type A influenza infection in the presence of type A virus-infected cells.

The type A influenza specific killer cells were selected by methods similar to those described for allogeneic killer cell lines<sup>3–8</sup>. Briefly, BALB/c donor mice were primed by infection with A/X-31 (H3N2, WHO nomenclature<sup>9</sup>) influenza virus and cytotoxic T cells (CTLs) were generated by culture of the primed spleen cells with A/X-31-infected lymphoblasts<sup>1</sup>. The cells were restimulated in the same way every 10–12 days ( $7.8 \times 10^5$  cells stimulated with  $1.5 \times 10^5$  ml irradiated infected lymphoblasts) and after 2 months the cells grew well in the absence of antigen in RPMI 1640 medium containing 10% fetal calf serum and 30% rat cell supernatant (RS). RS supernatant supporting the growth of the T cells was prepared by stimulating  $3 \times 10^6$  rat spleen cells per ml with  $3 \mu\text{g ml}^{-1}$  concanavalin A for 48 h (refs 3–8). The presence of T-killer cells were ascertained by assaying lysis of <sup>51</sup>Cr-labelled P815 (H-2<sup>d</sup>) mastocytoma cells infected with type A influenza virus, or non-histocompatible infected target cells. After 4 weeks the cells could be cloned on layers of syngeneic mouse peritoneal macrophages (irradiated with 1,600 rad) using two to five cells per well in 0.1 ml in a Linbro microplate. One of the clones (L4) was highly cytotoxic for influenza-infected cells at low killer/target cell ratios. On recloning the L4 killer cells, all the subclones lysed A/X-31-infected target cells (Table 1). The clones with the highest activity were grown and tested for their specificity. Clone L4 was found to show the same specificity as the mixed population of T-killer cells generated *in vitro* by culture of primed spleen cells with infected stimulators (Table 2). The L4 killer cells do not discriminate between the different subtypes and variants of influenza virus A. Target cells infected with any of the type A viruses are lysed equally well (USSR/70) (H1N1), Jap 305 (H2N2) or X-31 (H3N2), whereas cells infected with B/HK influenza virus, or H-2<sup>k</sup>-infected target cells are not attacked. Thus, H-2 restriction is preserved.

| L4/1  |     |                     | 62.9 |      |
| L4/2  |     |                     | 40.1 |      |
| L4/5  |     |                     | 44.2 |      |
| L4/9  |     | 33.9                |      |      |
| L4/11 |     |                     |      | 31.0 |
| L4/13 |     |                     |      | 35.9 |
| L4/14 |     |                     | 29.2 |      |

<sup>51</sup>Cr-labelled P815 target cells (H-2<sup>d</sup>) were infected with A/X-31 virus for 1 h. Following the addition of killer cells, lysis of  $2 \times 10^4$  target cells was assayed after 6 h by estimating the amount of <sup>51</sup>Cr released by the killer cells<sup>17</sup>. Control spontaneous release was 18%. Target cell lysis was expressed as %<sup>51</sup>Cr released = c.p.m. (experimental) - c.p.m. (spontaneous release)/c.p.m. (total) - c.p.m. (spontaneous release). K/T, killer/target cell ratio.

With time of culture, cytotoxicity and the rate of growth of L4 clones seem to decline. However, we have been able to grow the cells from frozen stock and to reclone on irradiated macrophages and have maintained highly cytotoxic clones for 8 months.

Although the established L4 cell line does not require antigen for its growth, because growth is supported by nonspecific and non-H-2- or strain-restricted growth factors produced by activated T cells, the cells clearly preserve their receptors for antigen recognition. First, L4 cells retain their killer specificity for type A influenza viruses, and second, 20% of the continuously growing T cells form clusters with P815 cells infected with type A virus but not with cells infected with influenza B virus (experiments with W. A. Taylor, using the method of Berke *et al.*<sup>10</sup>).

Growth and killer activity of L4 clones can also be induced in the presence of macrophages by stimulation with infected stimulator cells (irradiated spleen) and irradiated T-helper cells<sup>11</sup> from mice primed by infection with type A virus (Table 3). The L4 killer cells die in the absence of T-cell growth factor (RS) or irradiated T-helper cells plus antigen. The requirement for T-cell growth factor on its own distinguishes the T-cell clones from memory precursors of cytotoxic T cells in mice primed by infection. We find that the memory cells require antigen and T-cell growth factors for the generation of cytotoxic cells (B.A.A., unpublished results). This indicates that the continuously growing cells are at the last stage of differentiation. Fluorescent staining with monoclonal rat antibodies showed

**Table 2** Specificity of L4 killer cells, H-2 restriction and cross-reactivity between different type A influenza viruses

| 5  | -                                      | +                              | -  | 0                      |
| 5  | +                                      | +                              | -  | 0                      |

Stimulator cells are normal spleen cells irradiated (1,200 rad) and infected with A/X-31 influenza virus. Peritoneal exudate macrophages were seeded into microwells and irradiated at 1,600 rad before addition of the T-killer clone. +T-helper cells were spleen cells irradiated at 600 rad (ref. 11) and derived from mice primed intranasally by infection with A/X-31 virus 2 months previously. Target cell lysis on day 4 was assayed on  $10^4$  A/X-31 infected P815 mastocytoma cells, labelled with <sup>51</sup>Cr and added to the microwells after centrifuging the plate and removing the culture medium. Values for mean lysis by 6-12 culture wells are given ( $\pm$ s.e.).

that the L4 killer cells bear the Lyt 2 marker, but are Lyt 1 negative.

We have not been able to convert the L4 cytotoxic cells into memory cells by transferring them into syngeneic mice and challenging with influenza virus. However, we have been able to protect mice from death following lethal infection with A/X-31 virus. BALB/c mice were irradiated at 450 rad (Co source) and infected with A/X-31 influenza intranasally (25-50 haemagglutinin units in 100  $\mu$ l of 1/100 allantoic fluid). One day later, the mice received normal spleen cells, or our continuously growing cytotoxic T cells. Mice receiving no cells, or  $3 \times 10^6$  normal spleen cells intravenously died by day 17 or earlier, whereas the mice which had received  $3 \times 10^6$  L4 cytotoxic cells survived for more than 4 weeks. The cloned cells therefore show protective activity *in vivo* as do primed normal T cells restricted at the K and D end of H-2 (ref. 12).

It is not certain which viral protein is being recognized by A influenza-specific T-killer cells, but our killer cell line should help resolve this question. The internal matrix protein shared between the different type A viruses was previously thought to be recognized by cross-reactive T cells<sup>13,14</sup>; however, recent data indicate that killer T cells recognize a region of the haemagglutinin molecule homologous in all type A influenza viruses<sup>15-17</sup>.

L.Y.L. is a British Council-Chinese Exchange Scholar, Shanghai First Medical College. Monoclonal rat antibodies were provided by Dr L. Herzenberg.

# Reversible heat activation of alkaline phosphatase of *Dictyostelium discoideum* and its developmental implication

D. V. Mohan Das & Gerald Weeks

Department of Microbiology, University of British Columbia, Vancouver, Canada V6T 1W5

The activities of some enzymes increase during the development of the cellular slime mould, *Dictyostelium discoideum*. Because optimal specific activity is attained by each enzyme at a specific developmental stage<sup>1</sup>, development can be followed as a function of enzyme activity. The activity of one of these enzymes, alkaline phosphatase, increases markedly during the late stages of development, making it a potentially useful marker for terminal differentiation<sup>2,3</sup>. It has been suggested that this increase in activity is due to *de novo* enzyme synthesis because the increase in activity does not occur in the presence of inhibitors of RNA and protein synthesis<sup>2</sup>. However, we present evidence here of reversible heat activation of membrane-bound alkaline phosphatase which suggests that the increase in alkaline phosphatase activity may be due to an unmasking of pre-existing enzyme by a novel membrane regulatory mechanism.

Alkaline phosphatase is firmly membrane bound, and evidence suggests that it is located on both the plasma membrane<sup>3-5</sup> and the internal contractile vacuole membrane<sup>6</sup>. We found that there was a considerable decrease in alkaline phosphatase activity if a crude membrane preparation from vegetative-phase cells was stored at 4 °C. Activity was restored, however, if the membrane preparation was incubated at room temperature, and a dramatic increase in activity was observed if the enzyme was incubated at elevated temperatures. With increasing temperature the rate and amount of the enzyme activation increased (Fig. 1), reaching a maximum at 50 °C. Although not shown in

**Fig. 1** The effect of preincubation temperature on the activity of membrane-bound alkaline phosphatase. Crude membranes of vegetative cells of *D. discoideum*, strain Ax-2, were prepared as described previously<sup>8</sup>, resuspended in 5 mM Tris-Cl, pH 7.4, at 4 mg ml<sup>-1</sup> and incubated at 13.5 °C (○), 21 °C (□), 33.5 °C (△) or 50 °C (●). After the indicated periods of incubation, 0.1-ml aliquots of the membrane were assayed for alkaline phosphatase activity at 30 °C in a total assay volume of 1.0 ml as described previously<sup>3</sup>, with the addition of 30 mM NaF to inhibit acid phosphatase.

**Fig. 2** The reversible heat activation of alkaline phosphatase. Crude membrane preparations of vegetative cells were incubated at 50 °C and aliquots were removed at the indicated time points (○) and assayed for alkaline phosphatase activity at 30 °C. After 2 h of incubation at 50 °C (at the arrow) the preparation was divided into two and one portion (□) was incubated for 24 h at 0 °C followed by 1 h at 50 °C. At the indicated time points (□), aliquots were removed and assayed for alkaline phosphatase at 30 °C. The second sample (■) was rapidly cooled to -70 °C, maintained at -70 °C for 24 h and then incubated at 0 °C for 24 h, followed by 1 h at 50 °C. At the indicated time points (■), aliquots were assayed for alkaline phosphatase activity at 30 °C.

this experiment, activity at 50 °C is stable for up to 6 h. Incubation at 60 °C led to variable results (data not shown), whereas incubation at 70 °C resulted in a total inactivation of the enzyme.

This heat activation is totally reversible. A membrane preparation was heated at 50 °C for 2 h, and alkaline phosphatase activity increased markedly (Fig. 2). The preparation was then divided and one portion stored at 0 °C for 24 h, whereas the other was rapidly frozen in acetone/dry ice and stored at -70 °C for 24 h. The membrane fraction stored at 0 °C lost considerable alkaline phosphatase activity, but when reheated at 50 °C, activity was rapidly restored (Fig. 2). This heat activation-cold inactivation cycle could be repeated three times (data not shown) indicating that the phenomenon was totally reversible. The sample stored at -70 °C retained the elevated heat-activated level (Fig. 2), but when transferred to 0 °C, the activity declined markedly over a 24-h period. The enzyme could be reactivated by incubating at 50 °C.

Thus, membrane-bound alkaline phosphatase activity is markedly dependent on the temperature of storage. The mechanism of the reversible temperature-dependent activation is not known, but the factor(s) involved in the phenomenon are tightly membrane bound, as even after recentrifugation at 100,000g and resuspension in fresh buffer, both heat-activated and cold-inactivated membranes retained their capacity for the reversible activation or inactivation of the enzyme.

**Table 1** Comparison of the effects of preincubation at 50 °C and 0 °C on the alkaline phosphatase activity of intact membrane and butanol-extracted preparations

| Preparation   | No treatment | Preincubated at 50 °C for 60 min | Preincubated at 0 °C for 24 h |
|---|--------------|----------------------------------|-------------------------------|
| Specific activity of alkaline phosphatase (nmol min <sup>-1</sup> per mg protein) |              |                                  |                               |
| Intact membrane   | 9.2          | 74.0                             | 3.1                           |
| Butanol extract*  | 105.0        | 56.0                             | 96.0                          |

\* The butanol-extracted preparation was prepared by briefly vortexing a mixture of 0.4 ml butanol and 1.0 ml of a suspension of crude membranes in 5 mM Tris-Cl, pH 7.4 (10 mg protein ml<sup>-1</sup>). The aqueous phase was removed carefully, dialysed for 24 h against 0.01 M Tris-Cl, pH 7.4, and assayed for alkaline phosphatase activity at 30 °C after the indicated preincubation conditions. Over 70% of the activated membrane-bound alkaline phosphatase is solubilized by this procedure.

To investigate this phenomenon further, alkaline phosphatase activity was solubilized from the membrane by butanol treatment. Following butanol extraction the alkaline phosphatase activity of the aqueous phase was elevated to a level slightly higher than that observed following heat treatment (Table 1). When this solubilized enzyme was incubated at 0 °C for 24 h there was no loss in activity, whereas incubation at 50 °C for 60 min caused a reduction in activity, characteristics quite different from those of the enzyme of the intact membrane (Table 1). Thus, maintenance of membrane integrity seems to be essential for the expression of the reversible heat activation-cold inactivation of the enzyme.

The alkaline phosphatase activity of freshly prepared membranes from cells at later stages of development is considerably higher than that of vegetative cells, reaching peak levels at the culminating stages of development (Table 2). The activity of culminating cell membranes is not markedly responsive to heat activation or cold inactivation; there is no decrease in activity on storage at 0 °C for 24 h, and only a slight elevation on incubation at 50 °C for 1 h (Table 2). Alkaline phosphatase from pseudoplasmodial-stage cells is partially responsive to the heat activation phenomenon (Table 2). There is a slight cold-activation effect in pseudoplasmodial membranes but at present this phenomenon is not understood. As the peak activities of alkaline phosphatase in culminating membranes is of the same order of magnitude as the maximum activated levels of vegetative membranes, clearly vegetative-phase cells express only a small proportion of their potential alkaline phosphatase activity, whereas the culminating-phase cells express most of theirs. There is a twofold increase in the heat-treated levels of activity in culminating cells compared with vegetative cells (Table 2). This may indicate that heat treatment does not fully unmask the vegetative activity. Alternatively, as the amount of protein per cell decreases during differentiation<sup>7</sup>, the amount of membrane protein per cell probably decreases concomitantly, and the twofold increase in the specific activity of a membrane-bound enzyme would reflect no change in the amount of enzyme per cell. We have not investigated this possibility further due to the difficulty of determining accurately the yields of differentiating cells.

**Table 2** Comparison of the effects of preincubation of 0 °C and 50 °C on the alkaline phosphatase activity of membranes prepared from Ax-2 cells at various stages of development

| Developmental stage   | Developmental time (h) | Freshly prepared membranes | Preincubated at 0 °C for 24 h | Preincubated at 50 °C for 1 h |
|---|------------------------|----------------------------|-------------------------------|-------------------------------|
| Alkaline phosphatase specific activity (nmol min <sup>-1</sup> mg <sup>-1</sup> ) |                        |                            |                               |                               |
| Vegetative  | 0                      | 9.2                        | 3.1                           | 74.0                          |
| Pseudoplasmodium  | 22                     | 43.0                       | 71.0                          | 105.0                         |
| Preculmination  | 30                     | 108.0                      | 105.0                         | 139.0                         |
| Late culmination  | 34                     | 105.0                      | 92.5                          | 133.0                         |

It should be emphasized that the alkaline phosphatase activity of vegetative cells is the same, whether the membranes are prepared at 4 °C or 22 °C (data not shown), indicating that the low activity of freshly prepared vegetative membranes is not due to the low temperature of the preparative procedure<sup>8</sup>. We believe, therefore, that the apparent increase in alkaline phosphatase activity is due to unmasking of existing enzyme rather than to an increase in amount of enzyme. McCleod and Loomis<sup>9</sup> have recently presented evidence that the vegetative and developmentally determined enzymes are products of the same gene, a finding not inconsistent with the above suggestion.

This lack of correlation between the observed level of the enzyme and the amount of enzyme protein has also been reported during *D. discoideum* development (for example, see ref. 10). However, this is the first instance of an apparent unmasking of a presumptive developmentally regulated enzyme by heat treatment.

Although there is probably no direct physiological significance to the reversible heat activation of the membrane-bound alkaline phosphatase, this phenomenon apparently simulates the effect of a plasma membrane modification that occurs during development. This could involve the removal of a low-molecular-weight effector molecule or the dissociation of inactive protein aggregates within the plane of the membrane. We are investigating these possibilities.

We thank Dr G. Webb for helpful discussions and the National Science and Engineering Research Council of Canada for financial support.

## SV40 large T shares an antigenic determinant with a cellular protein of molecular weight 68,000

D. P. Lane\* & W. K. Hoeffler

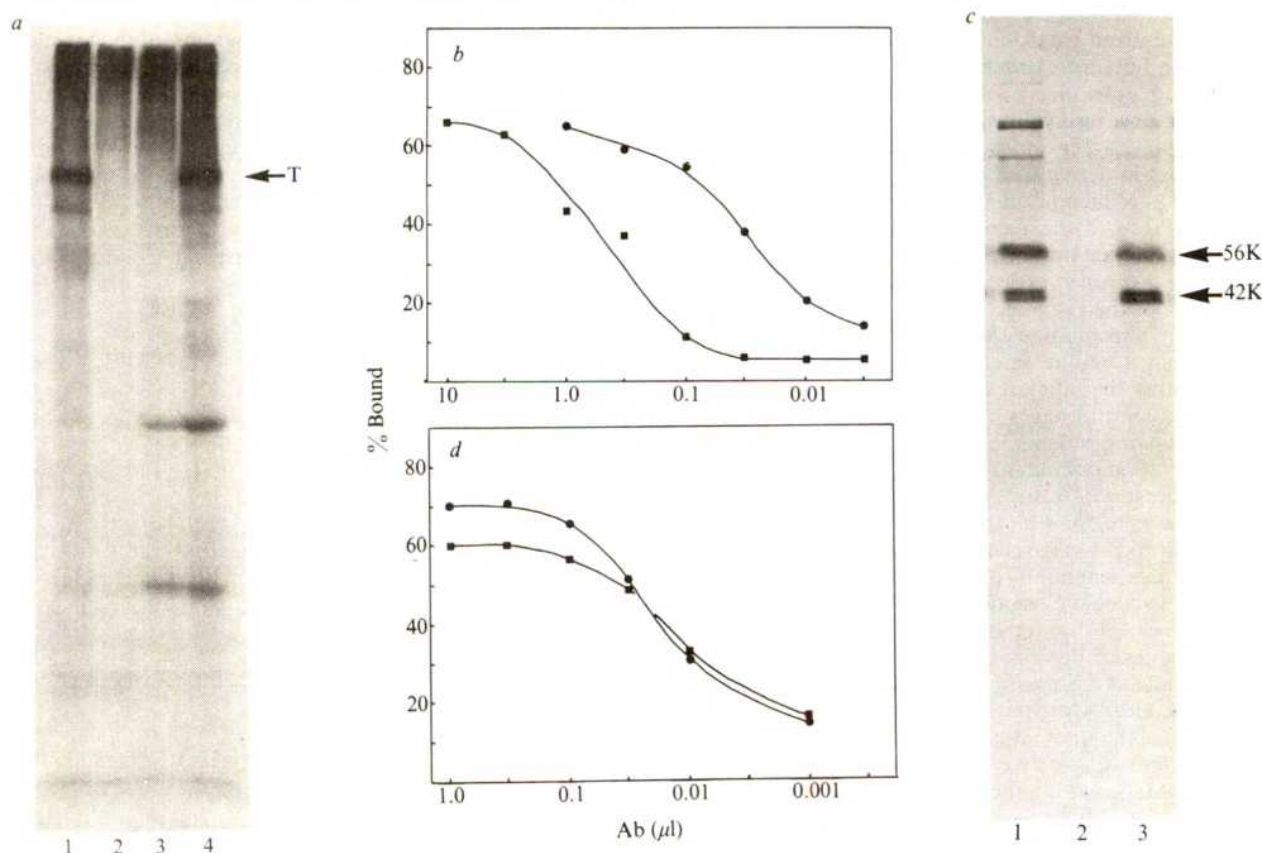

Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724

The large T protein coded by the early region of simian virus 40 (SV40) is involved in the induction and maintenance of cell transformation<sup>1</sup>. It is not clear which properties of T are important in causing the transformation, since the protein is multifunctional<sup>2-9</sup>. To clarify the action of T proteins in transformation, we have prepared several monoclonal antibodies directed against different regions of the T molecule. One of these antibodies, DL 3C4, recognizes an antigenic determinant on T that is also present on a host cell protein of molecular weight 68,000. This cross-reactive 68K protein is located within the nucleus of all mammalian cell types examined and has a characteristic granular distribution as shown by immunofluorescence. The antigenic determinant recognized by DL 3C4 is resistant to denaturation. Studies on Adeno-SV40 hybrid viruses show that the antigenic site on T is coded for by sequences located between 0.44 and 0.29 on the SV40 map.

The cell line producing the monoclonal antibody DL 3C4 was derived from a fusion between the HAT (hypoxanthine, aminopterin and thymidine)-sensitive myeloma cell line Sp2/O-Ag14 (refs 10-12) and spleen cells from a BALB/c mouse which had been hyperimmunized with the T antigen-related protein purified from Ad2<sup>+</sup> D2-infected HeLa cells<sup>5</sup>. Ten days after fusion cell culture supernatants were screened, using an indirect immunofluorescence test, for antibodies capable of staining the nuclei of SV40-transformed cells (SV80). The supernatants from 11 out of 96 wells were positive by this test and the cells from these wells were cloned using a soft-agarose method. (A detailed description of the methods will be published elsewhere, D. L., in preparation.)

\* Present address: Department of Zoology and Cancer Research Campaign Eukaryotic Molecular Genetics Research Group, Imperial College, London SW7 2AZ, UK.

**Fig. 1** Monoclonal antibody 3C4 binds to a specific region of SV40 large T antigen. *a*, SV80 cells, in a 60-mm Petri dish, were labelled for 1 h in phosphate minus E4 medium with 1 mCi of  $^{32}\text{P}$  and the labelled proteins extracted in 1 ml of 1% NP40, 120 mM NaCl, 50 mM Tris, pH 8.0. 100  $\mu\text{l}$  of the extract were incubated with (1) 10  $\mu\text{l}$  hamster anti-tumour serum, (2) 10  $\mu\text{l}$  normal hamster serum, (3) 50  $\mu\text{l}$  E4 medium and (4) 50  $\mu\text{l}$  supernatant E4 medium from a culture of 3C4 cells. After 1 h at room temperature 20  $\mu\text{l}$  of rabbit anti-mouse immunoglobulin serum (Rb $\alpha$  Mlg) were added to tubes (3) and (4) as 3C4 does not bind to protein A directly and then 1 h later 40  $\mu\text{l}$  of a 10% suspension of fixed *Staphylococcus aureus* Cowan 1 (ref. 21) were added. The bacteria were collected by centrifugation, washed four times in NET buffer<sup>21</sup> and the adsorbed immune complexes eluted by boiling in 50  $\mu\text{l}$  of SDS-gel sample buffer. The eluted proteins were analysed on a 15% polyacrylamide slab gel<sup>20</sup> and the labelled proteins detected by autoradiography of the stained fixed and dried gel. (The minor band below large T is a 73K breakdown product of T). *b*, Purified  $^{35}\text{S}$ -labelled large T antigen was isolated by immunoprecipitation and preparative SDS-gel electrophoresis from lysates of  $^{35}\text{S}$ -labelled SV40-infected CV1 cells as before<sup>13</sup>. It was then used to titrate the relative T-binding capacity of a rabbit antibody to large T (■) and of the monoclonal antibody 3C4 (●). The monoclonal antibody was used as the ascites fluid from a BALB/c mouse which had been injected intraperitoneally 10 days earlier with  $10^7$  3C4 cells. The radioimmunoassay was as described previously except in the case of the monoclonal antibody 20  $\mu\text{l}$  of Rb $\alpha$  Mlg were added, 1 h before the addition of 50  $\mu\text{l}$  SAC. Input was 1,000 c.p.m. of T. *c*, A 60-mm Petri dish contained HeLa cells, labelled with 500  $\mu\text{Ci}$  of  $^{35}\text{S}$ -methionine in met E4 medium 30 h after infection with Ad2<sup>+</sup>ND2 virus. After labelling for 1 h the labelled proteins were extracted as described in *a* and immunoprecipitated with (1) 10  $\mu\text{l}$  rabbit anti-T serum, (2) 20  $\mu\text{l}$  Rb $\alpha$  Mlg, and (3) 0.1  $\mu\text{l}$  3C4 ascites fluid + 20  $\mu\text{l}$  Rb $\alpha$  Mlg. The antibody-bound proteins were collected and analysed as in *a* except that a 10% SDS-polyacrylamide gel was used. *d*, Purified  $^{35}\text{S}$ -labelled 56K and 42K T-related proteins were isolated from extracts of  $^{35}\text{S}$ -labelled Ad2<sup>+</sup>ND2-infected HeLa cells as described for large T in *b*. The isolated proteins were then individually used in the radioimmunoassay to titrate the 3C4 ascites fluid binding to (■), the 56K protein (input 2,070 c.p.m.) and to (●), the 42K protein (input 2,360 c.p.m.).

The hybridoma cell line DL 3C4 has been cloned four times and grows well in culture. When injected into pristane-primed mice it induces an ascites tumour and the ascites fluid contains extremely high titres of the antibody ( $>1/10^4$  in the immunofluorescence test). The antibody synthesized by 3C4 specifically immunoprecipitates T antigen from lysates of  $^{32}\text{P}$ -labelled SV80 cells (Fig. 1*a*) and confirmation of its specificity for large T was obtained by radioimmunoassay<sup>13</sup>. The ascites fluid and supernatant tissue culture media of 3C4 cells were able to bind specifically pure  $^{35}\text{S}$ -labelled T antigen. (Isolated from  $^{35}\text{S}$ -methionine-labelled SV40-infected monkey cells by immunoprecipitation with a defined anti-T serum<sup>13</sup> followed by SDS-gel electrophoresis.) Figure 1*b* shows the titration 3C4 ascites fluid in such a radioimmunoassay. The monoclonal antibody could also immunoprecipitate the T-related proteins of molecular weights 56,000 and 42,000 present in extracts of Ad2<sup>+</sup>ND2-infected HeLa cells (Fig. 1*c*). Furthermore the antibody bound specifically to both polypeptides after they had been isolated by immunoprecipitation and elution from SDS gels (Fig. 1*d*). These experiments show that the 3C4 antibody

recognizes a determinant on T which is coded by the SV40 DNA present in the Ad2<sup>+</sup>ND2 virus (0.44–0.11 map units)<sup>14</sup> and which is resistant to the denaturing effects of SDS-gel electrophoresis. The 3C4 antibody did not immunoprecipitate or bind to the 30,000-molecular weight T-related protein synthesized in Ad2<sup>+</sup>ND1-infected cells (data not shown) and it is reasonable to assume that the determinant is therefore not coded by the SV40 DNA in this virus (0.29–0.11 map units)<sup>15</sup>. This approximately localizes the region coding for the determinant to sequences between 0.44 and 0.29 on the SV40 map. The determinant must be present on the majority of T-antigen molecules as the monoclonal antibody can bind the same proportion of the isolated  $^{35}\text{S}$ -labelled T antigens as a variety of other anti-T sera (Fig. 1).

Having observed the specificity of 3C4 for a particular region of T antigen, it was surprising to discover that the antibody gave a positive specific nuclear fluorescent staining pattern on a wide variety of different cell types that do not contain SV40 DNA or the SV40 T antigen. Figure 2 shows examples of this staining pattern on two different mammalian cell lines: KA31 cells are RNA-virus transformed murine fibroblast cells and PtK1 cells

are untransformed kidney epithelium cells from the marsupial *Potorous tridactylis*<sup>16</sup>. In both lines, especially PtK1 cells, the staining pattern is clearly nuclear and strikingly granular. Various cell lines, including cells of human, monkey and rat origin, all show the positive nuclear staining pattern, so the determinant being recognized is clearly highly conserved in the mammals. None of the other anti-T monoclonal antibodies examined, nor a variety of conventional anti-T sera, show such positive reactions on these cells, so the effect seems to be restricted to the DL 3C4 monoclonal antibody.

The species recognized by 3C4 in one of these SV40 T antigen-negative cell lines was identified using the immunautoradiography technique described by Burrige<sup>17</sup>. A single protein of molecular weight 68,000 is detected in extracts of mouse L cells (Fig. 3). Attempts to identify this protein by immunoprecipitation of conventional NP40 lysates of these cells were only partially effective. The protein is present in low concentration and poorly solubilized by buffers that effectively extract the viral T antigen from SV40-infected or -transformed cells, most of the antigen remaining in the insoluble pellet.

One hypothesis to explain the apparent dual specificity of 3C4 for the virally coded SV40 T antigen and the 68K host cell protein is that these two proteins share a common structural

**Fig. 2** Detection of a T-related protein in the nuclei of cells that do not contain SV40 DNA. Cells for immunofluorescence were grown on glass coverslips, washed in PBS, fixed in a 1:1 mixture of acetone and methanol at room temperature for 2 min, then overlaid with a 1/50 dilution of 3C4 ascites fluid. After 20 min of incubation the coverslips were washed in phosphate-buffered saline (PBS) and then overlaid with a 1/30 dilution of rhodamine-conjugated rabbit antibody to mouse immunoglobulin (Cappel). After a 20-min incubation the coverslips were washed in PBS and then with distilled water before mounting in gelvatol (Monsanto Chemicals) on clean glass slides. The coverslips were examined under a fluorescence microscope. *a*, Staining of KA31 cells. *b*, Staining pattern of PtK-1 cells.

**Fig. 3** Immunautoradiographic detection of the protein bound by 3C4 in cells that do not contain T-antigen. A complete nuclease-treated extract of mouse L cells, solubilized in sample buffer, was electrophoresed on a 10% SDS-polyacrylamide gel. Track 1, 40  $\mu$ l L cell extract ( $2 \times 10^5$  cells). Track 2, Marker proteins: 200K, 130K, 94K, 45K, 30K, 21K. *a*, Shows the gel stained with Coomassie blue. In *b*, the same gel strip was fixed lightly, equilibrated, and then overlaid first with monoclonal antibody DL 3C4 (as tissue culture supernatant) for 4 h and then after extensive washing in Tris-buffered saline it was overlaid with  $^{125}$ I-labelled rabbit anti-mouse immunoglobulin antibody for 3 h. After further extensive washing, the gel strip was stained dried and autoradiographed. *b*, Shows the result of a 46-h exposure to Kodak XR-1 film with a lightening-plus intensification screen at  $-70^\circ\text{C}$ . The method used is precisely that of Burrige<sup>17</sup>.

element that forms the antigenic site recognized by 3C4 antibody. That extracts of cells that did not contain T could, nevertheless, inhibit the binding of 3C4 to purified  $^{35}\text{S}$ -labelled T antigen (Fig. 4) supports this hypothesis. This result forms the basis of a radioimmunoassay for the host cell protein and eliminates a trivial explanation for the pattern of 3C4 reactivity—that the cell line produces two different antibodies, one specific for T and one specific for the 68K protein. Possibly some conventional anti-T sera have arisen that recognize this cross-reactive 68K protein. Indeed Renart *et al.*<sup>18</sup>, using a novel gel-transfer technique, detected a 68K protein in T-negative cells. However, in these cases it would be difficult to define the basis of the reaction as the natural assumption would be that it represented a contaminating independent antibody activity rather than a cross-reaction.

The detection of a host cell protein sharing a common structure with a virally coded transforming gene product has already been described for the RNA tumour viruses and led to the hypothesis that the RNA virus has 'stolen' a host gene<sup>19</sup>. The present finding should not be interpreted in the same way, because, although the monoclonal antibody discussed here does recognize a structure common to a DNA virus oncogene and a normal host protein, the common structure may be very limited in extent. For example, most of the anti-T sera and the other anti-T monoclonal antibodies we have isolated do not recognize the 68K species and the T protein therefore has several unique antigenic determinants.

**Fig. 4** Competition radioimmunoassay to detect the T-related protein. The HeLa cell extract was prepared by lysing  $10^9$  uninfected cells (grown in suspension culture) in 15 ml buffer (0.01 M phosphate, pH 7.0, 0.25% NP40 and 1 mM EDTA) on ice, centrifuging at 10,000g for 30 min and taking the supernatant fraction. Varying amounts of this cell extract were then mixed with a fixed amount of  $^{35}$ S-labelled purified large T (isolated as in Fig. 1b) and sufficient 3C4 antibody added to precipitate 50% of the large T in the absence of any competition. The radioimmunoassay was then carried out as described<sup>13</sup>. Each point shows the mean and  $\pm$ s.d. of a triplicate determination.

The extreme evolutionary conservation of the determinant recognized by 3C4 and the unusual nuclear localization of the host protein make it unlikely that the cross-reactivity is fortuitous, rather we would propose that the 68K protein and T share some common function. This function would involve an interaction with another host cell component and be highly conserved in evolution. In this model the interaction would be mediated through the region of T or of the 68K protein that form the 3C4 binding site; the SV40 T antigen thus mimics a structure on the host cell protein to usurp its function and thereby modify an aspect of the cells behaviour to suit the virus. Initial studies on the monoclonal antibody and the 68K protein support this: (1) 3C4 antibody is a potent inhibitor of the ATPase activity of the T-related protein made in Ad2<sup>+</sup>D2-infected Hela cells (R. Tjian, personal communication). (2) The intensity of nuclear fluorescence seen with the antibody varies with the growth state of the cell, so that nuclei of quiescent rat embryo fibroblasts are barely positive whereas the same cells growing exponentially stain brightly. The 68K protein may be involved in the initiation of host DNA synthesis in much the same way as the T protein acts in the initiation of viral DNA synthesis. The two proteins would then share a common need to interact with the host cell DNA replication machine. Clearly the determination of the function of the 68K protein may aid our understanding of the role of T antigen both in lytic infection and in transformation.

We thank Dr P. Beverley, Dr Clive Slaughter and Dr R. Kennett for advice and help with the hybridization technique, Dr E. B. Lane for help with the immunautoradiography, and all our colleagues at Cold Spring Harbor for supporting the project. Dr R. Kennett provided myeloma cell line Sp2/O-Ag14, Dr M. Wigler the L cells, Dr E. B. Lane the PtK-1 cells, and the pure D2 protein was a gift from R. Tjian and A. Robbins. This study was financed by the Cancer Center Grant to Cold Spring Harbor; D.P.L. was supported by a Post-doctoral Fellowship from the Cancer Research Institute Inc. and thanks the Department of Zoology, Imperial College, London, UK for granting him leave of absence.

## Mutants of avian myelocytomatosis virus with smaller gag gene-related proteins have an altered transforming ability

Gary Ramsay\*, Thomas Graf† & Michael J. Hayman\*

† Institut Für Virusforschung, Deutsches Krebsforschungszentrum, Im Neuenheimer Feld 280, 6900 Heidelberg, FRG

Avian myelocytomatosis virus strain MC29 is a replication-defective<sup>1</sup> avian oncovirus which in newborn chickens causes myelocytomatosis and liver and kidney tumours<sup>2,3</sup>. *In vitro* infection of bone marrow cells gives rise to colonies of transformed macrophage-like cells<sup>4</sup>, and cloned virus is also capable of transforming fibroblasts<sup>5</sup>. The genome of MC29 contains cellular sequences<sup>6–8</sup> which are closely related to those in other defective leukaemia viruses with similar transforming spectra. Consequently, these cellular sequences have been postulated to represent a new oncogene which has been designated *mac*, for macrophage transformation<sup>4,9</sup>. MC29-transformed cells contain a gag gene-related protein of a 110,000 molecular weight (MW) (p110)<sup>10</sup>, which by tryptic peptide analysis has been shown to be a fusion product comprised of gag gene-derived sequences and sequences which are presumed to be coded by the adjacent *mac* gene<sup>11,12</sup>. These findings suggest that this protein may be implicated in transformation by MC29. We now describe three mutants of MC29 that synthesize smaller gag gene-related proteins. These mutants have an altered ability to transform bone marrow cells but not fibroblasts. This demonstrates for the first time a direct involvement of the p110 protein of MC29 in transformation.

The starting point of our studies was the observation that the Q10 cell line, a MC29-transformed quail fibroblast line producing MC29 plus MC29 associated helper virus (MCAV)<sup>10</sup>, on prolonged periods in culture synthesized smaller gag gene-related proteins in addition to p110. To determine whether we could isolate from this cell line virus mutants that would direct the synthesis of these smaller proteins, we infected fresh quail fibroblasts at a low multiplicity of infection and analysed single transformed clones for the synthesis of the gag-related proteins. Of 12 clones analysed, 6 produced a protein smaller than p110. Figure 1 shows an analysis by immune precipitation of non-producer clones transformed by three of the mutants (non-producer cells being cells transformed by MC29 but unable to release infectious virus due to the absence of helper virus). Cells transformed by MC29 virus clones 10A, 10C and 10H contained proteins of respective approximate MWs 100,000, 95,000 and 90,000. These proteins were shown to be related to the MC29 p110 protein by tryptic peptide analysis which revealed that they contained gag- and *mac*-specific peptides (data to be published elsewhere).

**Fig. 1** Altered gag gene-related proteins synthesized in three clones of quail fibroblasts infected with MC29 virus derived from the MC29 Q10 line. Virus was collected from the supernatant fluids of the MC29 (MCAV) infected quail fibroblast line Q10 developed by Bister *et al.*<sup>10</sup>, and used to infect fresh quail embryo cells at various dilutions of the virus. Foci of transformed cells were isolated 10 days later from dishes (50 mm) containing less than 10 foci and grown up to approximately  $2 \times 10^7$  cells. Clones were screened for p110-related proteins by radioimmunoprecipitation analysis. For this,  $5 \times 10^6$  cells were labelled with  $^{35}\text{S}$ -methionine for 60 min and gag-related proteins immunoprecipitated by anti-virus serum and analysed by SDS-polyacrylamide gel electrophoresis as detailed elsewhere<sup>10</sup>. Immunoprecipitates were made using either normal rabbit serum (a) or rabbit anti-RSV serum (b).

The mutant MC29 genomes were rescued from the non-producer cells by superinfection with the helper virus *td* B77 and the rescued viruses tested for their ability to transform fibroblasts and bone marrow cells in comparison with wild-type virus. Table 1 shows that although the three mutant viruses still transform fibroblasts with titres similar to wild-type virus they transform haematopoietic cells at an approximately 100-fold reduced efficiency. Wild-type MC29 transforms both cell types with roughly equal efficiency. In addition, the colonies of bone marrow cells transformed by the mutant viruses were smaller than the wild-type colonies and proved difficult to grow. This difference in efficiency of transformation of bone marrow cells can also be shown directly on transformation of chick embryo

**Table 1** Transforming ability of the MC29 mutants assayed on chick embryo cells and chick bone marrow cells

| Virus                     | Transforming activity                    |   |   |       |
|---------------------------|--|---|---|-------|
|                           | Chicken embryo cells                     |   | Chicken bone marrow cells                   |       |
|                           | Fibroblasts foci (FFU ml <sup>-1</sup> ) | Macrophage foci (FFU ml <sup>-1</sup> ) | Macrophage colonies (CFU ml <sup>-1</sup> ) | Ratio |
| wt MC29 ( <i>td</i> B77)* | $2.3 \times 10^3$                        | $1.9 \times 10^3$                       | $2 \times 10^3$                             | 0.9   |
| wt MC29 (RAV-2)           | $1.3 \times 10^6$                        | $7.0 \times 10^5$                       | NT  | 0.5   |
| MC29-10A ( <i>td</i> B77) | $5 \times 10^4$                          | $3.2 \times 10^2$                       | $6 \times 10^2$                             | 0.009 |
| MC29-10C ( <i>td</i> B77) | $1 \times 10^6$                          | NT                                      | $6 \times 10^3$                             | 0.006 |
| MC29-10H ( <i>td</i> B77) | $1 \times 10^4$                          | $2 \times 10^2$                         | $5 \times 10^1$                             | 0.01  |

Non-producer clones of quail fibroblasts were superinfected with the avian leukosis virus *td* B77, passaged once and virus collected from the supernatant fluids 5–7 days later. FFU, focus-forming units. Titres were obtained following serial 10-fold dilutions of the virus stocks as described<sup>5</sup>. CFU, colony-forming units. The ratio was calculated by dividing the macrophage transforming titre, from CEC and bone marrow, by the fibroblast transforming titre. NT, not tested.

\* The wild-type virus used was derived either from the Q8 fibroblast line<sup>10</sup> superinfected with *td*B77 or from a MC29 (RAV-2)-producing macrophage cell line (H. Beug *et al.*, in preparation).

cells (CEC) that contain a mixture of cell types, including fibroblasts and macrophage-like cells (Table 1). Wild-type MC29 can transform both these cell types giving rise to small tight colonies of fibroblasts and large diffuse colonies of macrophage-like cells<sup>5</sup>. Figure 2 shows that CEC infected by two of these mutants, 10A and 10H, give rise exclusively to small tight fibroblast foci (Fig. 2a, b), whereas, as expected, wt MC29 gave rise to both types of focus (Fig. 2c). Cells newly infected with the mutant pseudotypes synthesized gag-related proteins corresponding in MW to those detected in the original isolates (unpublished observations).

The finding that a deletion in the p110 protein of MC29 leads to a large reduction in the macrophage transforming ability of the virus without affecting its fibroblast transforming potential could be taken to indicate that there are two separate gene products responsible for the transformation of different host cells. The fact that no messenger RNA other than that which codes for the MC29 p110 protein has been found in transformed cells (D. Stehelin *et al.*, personal communication) argues against this possibility. Another possibility is that there are domains in the molecule which are required for macrophage but not for fibroblast transformation. A third, not necessarily mutually exclusive alternative is that more transforming activity is required to transform bone marrow cells than is required to transform fibroblasts. The deletion observed in our mutants could have reduced the biological activity of the gag-related protein to a level which is insufficient to transform macrophages efficiently. The isolation of further DLV mutants altered in their ability to transform fibroblasts but still able to transform bone marrow cells would be useful in resolving this question. Interestingly, a mutant of avian erythroblastosis virus has been isolated which has also lost the ability to transform bone marrow cells but is still able to transform fibroblasts<sup>13</sup>. This mutant also has a deletion in the gag gene-related protein (p75) of this particular virus<sup>14</sup>.

**Fig. 2** Foci of chick embryo cells infected with mutants of MC29. The focus assay was prepared as described earlier<sup>5</sup> and pictures taken 10 days after infection. a, Foci induced by *td* 10A; b, by *td* 10H; and c, by wt MC29. All dishes were inoculated with 0.2 ml of virus containing approximately 200 FFU. d, Uninfected control. The foci in a and b as well as the small foci in c (indicated by the arrows) represent fibroblast foci. The large plaque-like foci seen only in c represent foci derived from transformed macrophages.

Studies are under way to locate the alterations in the proteins of the MC29 mutants by tryptic peptide mapping techniques and oligonucleotide mapping. Preliminary results indicate that the mutant proteins have lost several *mac*-specific peptides and have gained a *gag*-specific peptide and this can be correlated with a deletion(s) in the *mac* sequences in the genomic RNA (G.R., K. Bister, P. H. Duesberg and M.J.H., preliminary observations). This could indicate that our MC29 mutants arose by crossing-over between helper leukemia virus and the MC29 genome.

We thank Eva Korzeniewska and Gay Kitchener for technical assistance, Dr H. Beug for helpful discussions, Drs G. Peters and J. Wyke for their advice on preparing the manuscript and Joyce Newton for typing the manuscript.

## X-chromosome inactivation in extra-embryonic membranes of diploid parthenogenetic mouse embryos demonstrated by differential staining

S. Rastan\*, M. H. Kaufman†, A. H. Handyside† & M. F. Lyon\*

\*MRC Radiobiology Unit, Harwell, Didcot, Oxon OX11 0RD, UK

†Department of Anatomy, University of Cambridge, Cambridge CB2 3DY, UK

In somatic cells of female mammals one of the two X chromosomes is genetically inactive and heterochromatic, resulting in dosage compensation for X-linked genes<sup>1-3</sup>. In marsupials the paternally derived X chromosome is preferentially inactivated. In eutherian mammals, although either X chromosome can be inactivated at random in somatic cells, preferential inactivation of the paternally derived X chromosome has been demonstrated cytologically in mouse and rat yolk sac<sup>4,6</sup> and mouse chorion<sup>5</sup> and biochemically in mouse yolk sac<sup>7</sup>, chorionic ectoderm<sup>8</sup> and trophoblast. In mouse yolk sac the non-random element has been shown both biochemically<sup>7</sup> and cytologically<sup>9</sup> to be confined to the endoderm layer in which there is almost total paternal X-chromosome inactivation. We have therefore looked at X-chromosome activity in the separated yolk sac layers of diploid parthenogenetic mouse embryos in which both X chromosomes are maternally derived. Kaufman *et al.*<sup>10</sup> have demonstrated X inactivation in somatic cells of diploid parthenogenetic embryos, and we have used a modification of Kanda's method<sup>11</sup>, which renders the presumptive inactive X dark staining, to reveal an inactive X chromosome in both endoderm and mesoderm layers of separated yolk sacs from parthenogenones. Thus even in tissues in which there is normally total non-random paternal X inactivation, in the absence of a paternally derived X chromosome a maternally derived X can be inactivated.

Kanda identified the inactive X chromosome at metaphase in female mice<sup>11</sup> and other rodents<sup>12</sup> by treating bone marrow cells with hot hypotonic potassium chloride solution before fixation. The inactive X chromosome then stained much more darkly with Giemsa dyes than the other chromosomes in the cell. The modification of the Kanda method for use with embryonic material involved placing the whole embryo and/or embryonic membranes for 90 min in culture medium 199 (Flow Laboratories) to which colchicine had been added ( $4 \mu\text{g ml}^{-1}$  final concentration) to accumulate metaphases. The embryos were then placed individually in Petri dishes containing 0.5% (w/v) potassium chloride solution at room temperature and incubated in a water bath at 50°C for 15 min, followed by fixation in freshly made 3:1 absolute ethanol/glacial acetic acid solution. After fixation the embryos were isolated, touched lightly to filter paper to remove excess fixative and disaggregated in 0.5 ml of 60% acetic acid for 5 min. Chromosome spreads were made by allowing small drops of the acetic acid mixture to evaporate on slides placed on a 40°C hot plate. The preparations were stained in 2% Giemsa buffered at pH 6.8 for 20 min.

A dark-staining X chromosome was seen in more than 80% of metaphase cells from female embryos at 5½, 6½, 7½ and 13½ days post-coitum (p.c.) (Table 1 and Fig. 1a, b). Strong evidence that the dark staining chromosome is the inactive X chromosome is that it is seen in such a high proportion of XX female cells, but not in XO female cells nor XY male cells. A dark staining X chromosome was also present in more than 75% of cells from a bone marrow preparation of an adult XX male mouse carrying *Sxr*, the autosomal gene for sex reversal<sup>13</sup>.

Five experimental diploid parthenogenetic embryos were produced by the method of Kaufman *et al.*<sup>14</sup> by suppression of second polar body formation, and dissected out of their decidua at a stage equivalent to 9½-10½-day gestation (10-25 somites present). Their yolk sacs were removed, washed in medium 199 and placed in medium 199 with colchicine ( $4 \mu\text{g ml}^{-1}$  final concentration) for 3 h at room temperature to accumulate metaphases. The yolk sacs were then separated into their endodermal and mesodermal components by partial digestion for 3 h in a mixture of 2.5% pancreatin and 0.5% trypsin (w/v) made up in  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ -free Tyrode solution at 4°C<sup>15</sup>, followed by dissection with watchmaker's forceps. The cleanly separated cell layers were then individually treated by the modified Kanda method, as described above. Chromosome spreads from the two separated yolk sac components from normal fertilized zygotes at the same developmental stage were also obtained. The slides were all stained in 2% Giemsa at pH 6.8 for 20 min, randomized and coded, and cells at metaphase were scored for the presence or absence of a dark staining X chromosome (Table 2). A dark staining X

Table 1 Staining of metaphase cells from female embryos

| Age of embryos (days p.c.) | No. of female embryos | Total metaphases | Metaphases with a dark X chromosome | Per cent with a dark X chromosome |

| 5½                         | 8                     | 221              | 192                                 | 86.88                             |
| 6½                         | 13                    | 1,188            | 1,019                               | 85.77                             |
| 7½                         | 6                     | 545              | 455                                 | 83.49                             |
| 13½                        | 8                     | 598              | 495                                 | 82.78                             |

Virgin female mice of the 3H1 strain ( $F_1$  hybrids between two inbred strains, C3H/HeH and 101/H) were injected with 5 IU pregnant mare's serum gonadotropin (PMS) followed 44 h later by an injection of 5 IU human chorionic gonadotropin (HCG) to synchronize ovulation, and were mated to 3H1 males. Females were checked for vaginal plugs early the next morning, and the day of the plug was designated day ½. Pregnant females were killed by cervical dislocation at various stages of pregnancy, and the embryo was dissected out under a dissecting microscope. Whenever possible Reichert's membrane was removed to ensure that there was no contamination by maternal cells. The 13½-day embryos were sexed by dissecting out the gonad, which has visibly differentiated by this stage, and the earlier embryos were sexed cytologically.

**Table 2** Staining of metaphases from yolk sacs

| Tissue            | No. embryos     |          | No. metaphases scored |          | No. metaphases with a dark X chromosome |              |
|-------------------|-----------------|----------|-----------------------|----------|---|--------------|
|                   | Parthenogenones | Controls | Parthenogenones       | Controls | Parthenogenones (%)                     | Controls (%) |
| Yolk sac endoderm | 5               | 14       | 94                    | 914      | 76(80.85)                               | 742(81.18)   |
| Yolk sac mesoderm | 5               | 14       | 328                   | 675      | 255(77.74)                              | 558(82.67)   |

This table shows the number of cells at metaphase from parthenogenetic separated yolk sac endoderm and mesoderm exhibiting a dark-staining X chromosome after treatment with the modified Kanda method, compared with controls of fertilized material which have received the same treatment.

**Fig. 1** Metaphase cells showing an inactive dark-staining X chromosome after hypotonic treatment at 50 °C. *a*, Metaphase from a normal 5½-day p.c. embryo; *b*, metaphase from a normal 7½-day p.c. embryo; *c*, metaphase from the endoderm layer of diploid parthenogenetic yolk sac; and *d*, metaphase from the mesoderm layer of diploid parthenogenetic yolk sac.

chromosome was seen in 76 out of 94 metaphases in parthenogenetic yolk sac endoderm (Fig. 1c) and in 255 out of 328 metaphases scored from parthenogenetic yolk sac mesoderm (Fig. 1d). We therefore conclude that X-chromosome inactivation has taken place in both endodermally and mesodermally-derived layers of yolk sac from diploid parthenogenones.

Cooper<sup>16</sup> has suggested that passage of the X chromosome through male gametogenesis or fertilization led to imprinting of the paternal X chromosome and was an important factor in paternal X inactivation in marsupials. It has been further suggested that imprinting also occurs in eutherian mammals<sup>17</sup> and results in paternal X inactivation in those tissues of the embryo that differentiate early, such as yolk sac endoderm which is derived from the primitive endoderm<sup>18</sup>, but that cells of the embryo proper escape from imprinting before the time of X-chromosome differentiation so that in them X inactivation is random<sup>19,20</sup>. Our results show that even in a tissue such as yolk sac endoderm in which primary non-random inactivation of the paternal X is thought to occur, a maternal X chromosome can be inactivated in the absence of a paternal one. In our parthenogenetic material neither X chromosome could have been imprinted, either by passage through male gametogenesis, fertilization or re-entry of the polar body, and so we conclude that imprinting cannot be essential to the mechanism of X inactivation in the tissues in which non-random paternal X inactivation normally occurs. One cannot, however, assume that absence of an imprinted X chromosome has not affected X inactivation in any way; for example, is the onset of X inactivation

in these tissues delayed? Homozygous diploid uniparental mice, produced by the removal of one or other pronucleus after fertilization, followed by diploidization in cytochalasin B, are viable<sup>21</sup>, which suggests that X inactivation in all tissues has occurred normally. However, as no live-born mammalian parthenogenones have been produced so far, one cannot rule out the possibility that some abnormality of X inactivation is involved in their premature death.

We thank Mrs A. Burling for technical assistance.

## Structure of two adenovirus type 12 transforming polypeptides and their evolutionary implications

Michel Perricaudet, Jean-Michel le Moullec & Pierre Tiollais

Unité de Recombinaison et Expression Génétique, Institut Pasteur, 28 rue du Docteur Roux, 75724 Paris Cedex 15, France

Department of Microbiology, The Biomedical Center, Box 581, S-751 23 Uppsala, Sweden

The human adenoviruses are classified according to their nucleotide sequence homology and their oncogenic potential in rodents<sup>1,2</sup>. The left-hand end of the genome of the adenovirus types 5 (ad5), 7 (ad7) and 12 (ad12), which are respectively, non-oncogenic (subgroup C), weakly oncogenic (subgroup B) and highly oncogenic (subgroup A)<sup>3-5</sup>, contains all the genetic information needed to induce and maintain the transformed phenotype. This part of the genome contains the early transcription unit designated E<sub>1</sub>, which is subdivided into two transcription units E<sub>1</sub>A and E<sub>1</sub>B<sup>6</sup>. Two spliced mRNAs are transcribed from the E<sub>1</sub>A region which codes for several phos-

phorylated polypeptides. These polypeptides play a key role by controlling the expression of the other early transcription units<sup>7,8</sup>. The major role of region E<sub>1</sub>A in adenovirus cell transformation might be to activate the true transforming genes of the region E<sub>1</sub>B. An additional role probably consists of the activation of some cellular genes as a restriction fragment containing this region can immortalize rodent cells *in vitro*. An important question is why some adenoviruses are oncogenic and others are not. We report here differences in the structures of the E<sub>1</sub>A polypeptides from ad7 and ad12, compared to ad5, which may partially account for their differing oncogenicity.

To answer this question, we have cloned in *Escherichia coli* double-stranded complementary DNA (cDNA) copies of the transforming mRNAs from region E<sub>1</sub>A of ad12 and compared their structures and their translation products with those of the corresponding mRNAs of ad5 (ref. 9) and ad7 (ref. 10). The cloning procedure and the determination of the physical structure of the cDNA were as described in Fig. 1. The two clones designated 11 and 44 contain the longest inserts and describe two different spliced mRNAs of the region E<sub>1</sub>A. Structural study of the cloned cDNAs at the nucleotide level shows that the splicing events of the mRNAs result in the deletion of a markedly AT-rich region, between nucleotides 1,069 and 1,144, which contains many stop codons<sup>11</sup> (Fig. 2). In clone 44 position 976 (donor site D<sub>1</sub>) is spliced to position 1,144 (acceptor site A), and in clone 11 position 1,069 (donor site D<sub>2</sub>) is spliced to position 1,144 (Fig. 1). The sequence of the donor site D1 (UU ↓ GUAAGU) is unexpected as a pyrimidine precedes the dinucleotide GU. The sequence of the other donor site D2 (CA ↓ GUAAGU) is very similar to the prototype sequence for a donor site described by Seif *et al.*<sup>12</sup>.

**Fig. 1** Structure of the two mRNAs of the E<sub>1</sub>A region from ad12 genome. cDNA copies of RNA from ad12-infected KB cells, 8-h post-infection and grown in the presence of cycloheximide were synthesized as described elsewhere<sup>14</sup> except that RNA was not poly(A) selected. cDNA was inserted into the *Pst*I restriction site of plasmid pBR322 after dG-dC tailing with the terminal transferase<sup>9</sup>. The recombinant plasmids were propagated in the *E. coli* DP 50 bacterial strain. Bacterial clones containing ad12-specific sequences of the transforming region were identified by *in situ* hybridization using the *Eco*RI-C restriction fragment (0–16%) as a probe; 30 clones gave a positive hybridization signal. Subsequent hybridization using <sup>32</sup>P-labelled poly(dT) as a probe was then performed to detect clones containing a poly(A) tract. Six clones gave a positive signal. Plasmid was extracted from the 30 clones and analysed by restriction endonuclease digestion. The size of the insert was determined by sizing of the *Pst*I restriction fragment and the plasmids containing the longest cDNAs as well as a poly(A) tail were selected for further analysis. Plasmid, <sup>32</sup>P-labelled *in vitro* by nick translation, hybridized only to the *Hind*III-G restriction fragment (0–6.8% of the genome) and therefore must contain cDNA sequences corresponding to mRNA of region E<sub>1</sub>A. *a* Represents the physical map of a part of the left-hand end of the ad12 genome. *b* Represents the cDNA structure from clone 44. It is 900 base pairs long and possesses the *Ava*II restriction site at nucleotide 525, but not the *Ava*II restriction site at position 1,143 suggesting it is located in the intron. The five *Hinf*I restriction sites are present and the *Hinf*I DNA fragment located between positions 853 and 1,307 is about 150 base pairs shorter than the corresponding genomic DNA fragment suggesting that this fragment contains the splice junction. *c* Represents the cDNA structure from clone 11. It is 1,000 base pairs long and possesses the same restriction sites as clone 44. However, the *Hinf*I DNA fragment located between positions 853 and 1,307 is 75 base pairs shorter than the homologous genomic restriction fragment, suggesting that this fragment contains different splice junctions. The 5' end, the polyadenylation site and the splice points were located by the nucleotide sequence determination of the appropriate region. Sequence analysis was carried out according to the Maxam and Gilbert procedure<sup>15</sup>. The horizontal arrows show the strategy adopted for our sequencing approach. Due to the presence of tandem repeats at the splice points (GU in both mRNAs) it is not possible to pinpoint precisely the positions where splicing has taken place. However, by following the GU/AG rule, tentative location for the splice points can be established and are indicated by vertical arrows. Following this assumption, nucleotide 976 is connected to nucleotide 1,144 in the mRNA corresponding to the clone 44 (*b*) and nucleotide 1,069 is connected to nucleotide 1,144 in the mRNA corresponding to clone 11 (*c*).

**Fig. 2** The proposed primary structure for the two mRNAs and for the corresponding polypeptides of the ad12 E<sub>1</sub>A region. These structures are deduced from our analysis of the cDNA clones together with the nucleotide sequence for the left-hand end of ad12 DNA. The sequence which is absent in the shortest mRNA is underlined. The hexanucleotide AATAAA present close to the poly(A) junction of eukaryotic mRNA<sup>16</sup> is indicated by a box. Nucleotides which become connected after splicing are shown in boxes (see also Fig. 3). The nucleotide sequence is indexed according to the nomenclature of Sugisaki *et al.*<sup>17</sup>.

**Fig. 3** Comparison of the homologous regions for donor and acceptor sites of the mRNAs from the E<sub>1</sub>A early region of ad5, ad7 and ad12. The nucleotide sequences of the ad5 capping site are from ref. 18. The nucleotide sequences of the ad5 splicing and poly(A) sites are from ref. 9. The nucleotide sequences of the ad7 capping and splicing sites are deduced from comparing the homologous nucleotide sequences of ad5 (ref. 13), ad7 (ref. 10) and ad12 (ref. 11) genomes. The nucleotide A, position 1,017 of ad7 from the region homologous to the ad5 D<sub>1</sub> site, cannot be used as a splice donor site as it is followed by the dinucleotide GC. On the contrary the sequence UGUAAGU of the ad12 D<sub>1</sub> site (U: donor nucleotide) is found around the ad7 nucleotide U, position 1,062. The donor site D<sub>2</sub> and the acceptor site A of ad7 have been localized respectively at positions 1,155 and 1,249 by a similar method.

Sequence analysis from the *Pst*I cleavage sites of both clones 11 and 44 allowed us to describe the boundaries of the mRNAs. Sequencing gels revealed the same poly(A) addition sites for both mRNAs. However, it was not possible to predict exactly where the poly(A) addition had occurred because two As follow the G residue at position 1,455 in the DNA sequence<sup>11</sup> (Fig. 2) as is frequently the case for eukaryotic mRNAs. The poly(A) addition site is located 14–16 nucleotides after the typical hexanucleotide sequence AAUAAA. Note that two other hexanucleotide sequences AAUAAA are encountered at positions 1,397 and 1,241. However, no poly(A) addition seems to occur downstream of these positions, thus indicating that the hexanucleotide sequence alone may not be a sufficient signal for polyadenylation. Sequence analysis performed at the 5' ends of both cDNAs located the 5' boundaries at nucleotides 461 and 463, respectively, for clones 11 and 44, that is about 40 nucleotides upstream from the AUG presumed to be the initiation codon (Fig. 1). However, these positions probably do not represent the true 5' ends of the mRNAs because a few nucleotides are usually lost at the extremities during mRNA cloning. The cap site is probably located at position 445 as the sequence at this position is identical to the sequence at the cap site in region E<sub>1</sub>A of ad5 (Fig. 3).

A comparison of the sequences for donor and acceptor sites of ad5, ad7 and ad12 is very informative (Fig. 3). The results from our cloning experiments show that the donor sites D<sub>2</sub> and the acceptor sites A are located in homologous sequences in both serotypes 5 and 12 whereas the donor sites D<sub>1</sub> are not. Thus donor site D<sub>1</sub> is displaced 45 nucleotides further along the serotype 12 sequence as compared to the homologous sequence of serotype 5. Although the splices for the E<sub>1</sub>A mRNAs from ad7 have not yet been established by cloning experiments, they can be predicted by comparing the DNA sequences of the three serotypes 7, 12 and 5 (refs 10, 11 and 13, respectively) around the presumed splice points. Thus, the only alternatives are the positions 1,062 and 1,155 for donor sites D<sub>1</sub> and D<sub>2</sub> and nucleotide 1,249 for the acceptor site. The donor site D<sub>1</sub> would be located in homologous sequences in both serotypes 7 and 12 and the dinucleotide GU would in both cases be preceded by a U residue. The donor site D<sub>2</sub> and the acceptor site A would be located in homologous sequences in the three serotypes.

The established DNA sequence together with the positions of splice points allow us to predict the primary sequences of the polypeptides which are encoded by each of the ad12 E<sub>1</sub>A spliced mRNAs (Fig. 2)<sup>11</sup> and to compare them with those of the two other serotypes 5 (refs 13, 9) and 7 (ref. 10) to find common features (Fig. 4). In the three serotypes both mRNAs are translated before and after the splice. Thus for each serotype the two E<sub>1</sub>A polypeptides have identical amino- and carboxy-

**Fig. 4** Diagram showing the homologous amino acids occurring in the longest E<sub>1</sub>A polypeptides among the three adenovirus types 5, 7 and 12. Black areas (■) represent homologies and colourless areas non-homologies. Ile, Leu and Val, Ser and Thr, Asn and Gln, Asp and Glu, were respectively considered as similar amino acids. Gaps are left whenever necessary to maximize homology. The vertical arrow indicates the position where the intron is found in the genome. The black areas show the good conservation of the amino acid sequences of the three polypeptides. However, a deletion corresponding to about 40 amino acids and an insertion corresponding to about 20 amino acids are present in both ad7 and ad12 compared to ad5. The left part of the figure corresponds to the N-terminal end of the polypeptides. Scale bar denotes a peptide 10 amino acids long.

terminal ends, their only difference being an internal deletion due to different positions of the donor sites for splicing. A comparison of the amino acid sequences shows an important deletion located in the C-terminal part of the polypeptides, and an insertion and another deletion in homologous regions of ad7 and ad12 compared to ad5. However, several identical amino acid stretches are encountered along the three polypeptide sequences showing the existence of highly conserved regions. This suggests a common ancestor for these adenoviruses. The different locations of the splice sites and the differences observed in the primary structures of the polypeptides also suggest that subgroups A and B had some evolutionary steps in common. A scheme for the evolutionary path might be:

The different primary structures observed for the ad7 and ad12 E<sub>1</sub>A polypeptides compared to ad5 might explain in part the oncogenic properties of these serotypes. Nevertheless, a similar comparison of primary structures of ad12 E<sub>1</sub>B polypeptides with those of ad7 and ad5 is necessary. Among the 10,000 clones so far analysed, not one was found to contain sequences from region E<sub>1</sub>B. A hybridization experiment between single-stranded <sup>32</sup>P-DNA copies of ad12 mRNA and

ad12 HindIII restriction fragments, showed no signal for the HindIII-I restriction fragment (6.8–10.9% of the genome). This result suggests that the region E<sub>1</sub>B is not transcribed early during the lytic cycle. Therefore there may be a fundamental difference in the expression of region E<sub>1</sub>B in adenovirus subgroups A and C. Further studies of the protein products from the E<sub>1</sub>B region are clearly required to resolve this issue and we are currently extending our analysis to the region E<sub>1</sub>B.

This work was supported by grants from the Swedish Cancer Society, the Swedish MRC, the Délégation Générale à la Recherche Scientifique et Technique, the CNRS and INSERM. We thank Dr Beard for reverse transcriptase.

## Phorbol ester-induced differentiation of chronic lymphocytic leukaemia cells

Thomas H. Tötterman, Kenneth Nilsson & Christer Sundström

The Wallenberg Laboratory and the Departments of Internal Medicine and Pathology, University of Uppsala, Uppsala, Sweden

The croton oil-derived tumour-promoting agent 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) exerts pleiotropic effects on the differentiation and proliferation of both normal and malignant animal and human cells *in vitro*. TPA is mitogenic in nanomolar concentrations to chicken embryo fibroblasts<sup>1</sup> and human T lymphocytes<sup>2</sup> and inhibits the terminal differentiation of various committed embryonic cells<sup>3,4</sup> and mouse Friend erythroleukaemia<sup>5</sup> or myeloid leukaemia<sup>6</sup> cells. TPA induces a terminal cell differentiation in some murine<sup>7</sup> and human<sup>7–11</sup> myeloid leukaemia and histiocytic lymphoma cells<sup>12</sup>. We report here the effect of TPA on chronic lymphocytic leukaemia (CLL) biopsy cells *in vitro*. In four out of five CLL patients studied, TPA induced the appearance of 90–100% lymphoblastoid and plasmacytoid cells after 4 days of culture. Under the influence of TPA, 86–97% of the cells expressed with time increasing amounts of intracytoplasmic immunoglobulin (C-Ig) of the same phenotype as that detected on the surface (S-Ig) of fresh, non-induced CLL cells. A parallel decrease in both monoclonal S-Ig density and DNA synthesis of the CLL cells was observed. Electron microscopic studies showed a maturation towards plasma cells. We therefore conclude that TPA is capable of inducing differentiation of CLL cells *in vitro*.

Three patients with CLL (AK, EJ and MW) and one patient (EB) with prolymphocytic leukaemia (a clinical variant of CLL<sup>13</sup>) were selected for this study on the basis of high blood levels ( $>10^5 \text{ mm}^{-3}$ ) of monoclonal B lymphocytes. Blood mononuclear cells were separated by density-gradient centrifugation<sup>14</sup> and analysed for relative numbers of E rosetting<sup>15</sup> (on average 8%) and S-Ig-positive cells (on average 91% stained cells using polyvalent fluorescein isothiocyanate (FITC)-conjugated rabbit anti-human Ig F(ab')<sub>2</sub> fragment, Kallestad). The S-Ig isotypes of the cells were determined using fluorescent F(ab')<sub>2</sub> antisera specific for human heavy ( $\mu$ ,  $\delta$ ,  $\gamma$ ,  $\alpha$ ,  $\epsilon$ ) and light ( $\kappa$ ,  $\lambda$ ) chains (Kallestad; anti- $\epsilon$  serum produced by Behring).

In preliminary experiments, the cells were plated and cultured with different concentrations of TPA. Figure 1 shows that the maximal frequency of C-Ig-positive cells ( $>90\%$  at day 3) was found with a TPA concentration of  $1.6 \times 10^{-7} \text{ M}$ . This concentration was used in later experiments.

Figures 2, 3 and 4 demonstrate the morphological features of CLL cells exposed to TPA. Within 4–12 h after plating, most of the cells became larger and acquired variable shapes. About 70% formed free-floating or surface-adherent clusters which increased in size with time (Fig. 3b). MGG-stained cytocentrifuge preparations at day 1–2 revealed a rapid enlargement of the cytoplasm together with an increasing basophilia and the appearance of a prominent nucleolus (lymphoblastoid cells). At day 3–4, cells with a large basophilic and frequently vacuolized cytoplasm and an eccentrically located nucleus (plasmacytoid cells) dominated the cultures together with the lymphoblastoid cells; only ~5% small lymphocytes were observed (Figs 2, 3c). Morphologically mature plasma cells were, however, only rarely seen. The viability remained  $>90\%$  in both the TPA-treated and control cultures as judged by Trypan blue exclusion. The

The S-Ig isotype of the CLL cells is given in brackets for each of the four patients (EB, AK, EJ, MW). Fresh biopsy cells (day 0) or cells cultured (day 1–4) in the absence (control) or presence of TPA ( $1.6 \times 10^{-7}$  M) were stained for surface and cytoplasmic  $\mu$  chains using FITC-coupled goat anti-human  $\mu$  serum (F(ab')<sub>2</sub> fragment, Kallestad at dilutions 1:3 and 1:10, respectively). The proportion of stained cells (%) and mean intensity ( $I$ , relative units; 20–30 cells measured per sample) of cellular fluorescence were measured using a Zeiss surface fluorescence cytophotometer (UV light source HBO 100 W, excitation filter BG12, barrier filter 50; objectives Neofluar Ph2 40 $\times$  and Ph3 100 $\times$  for C-Ig and S-Ig, respectively). ND, not determined.

**Fig. 1** Effect of different concentrations of TPA on the relative number of CLL cells expressing monoclonal cytoplasmic immunoglobulin. ○, Patient AK (S-Ig isotype  $\mu, \delta, \lambda$ ); ●, patient EJ ( $\mu, \lambda$ ). CLL cells ( $10^6 \text{ ml}^{-1}$ ) were cultured on plastic Petri dishes in Ham's F-10 medium supplemented with 10% fetal calf serum, antibiotics and TPA (Sigma, stock solution  $1 \text{ mg ml}^{-1}$  dissolved in 100% ethanol) at indicated final dilutions. Cultures were collected on day 3. The cells were washed, cytocentrifuged on to microscope slides, fixed in ice-cold methanol:acetone (1:1) and stained for intracytoplasmic  $\mu$  (C- $\mu$ ) chains using specific 1:10 diluted FITC-conjugated rabbit anti-human  $\mu$  serum (F(ab')<sub>2</sub> fragment, Kallestad). Fluorescent cells were quantified using the microscope equipment described in Table 1 legend.

**Fig. 2** TPA-induced morphological differentiation of CLL cells. Relative distribution (means for four CLL patients) of small lymphocytes (open bars), lymphoblastoid cells (shaded bars) and plasmacytoid cells (closed bars) at different times of culture. Cells were cultured in the continuous presence of  $1.6 \times 10^{-7}$  M TPA, collected on days 1 and 4, cytocentrifuged on to microscope slides and stained with May-Grünwald-Giemsa (MGG). Differential counts were calculated from 250 scored cells. Day 0 = untreated biopsy cells.

**Fig. 3** Morphology of CLL cells (patient AK) cultured for three days in the presence of  $1.6 \times 10^{-7}$  M TPA. *a* and *b*, Cultures of living untreated and TPA-treated cells, respectively ( $\times 220$ ). *c*, TPA-treated cells stained with MGG ( $\times 660$ ). *d*, Immunofluorescence of TPA-treated cells stained for cytoplasmic  $\mu$  chains ( $\times 450$ ).

lymphoblastoid and plasmacytoid cells, but not the small fraction of small lymphocytes, stained strongly for C-Ig (Fig. 3d and Table 1). In control experiments, TPA-induced CLL cells (day 3–4) from the four patients were stained for C-Ig using monospecific antisera against the immunoglobulin heavy chains  $\mu$ ,  $\delta$ ,  $\gamma$ ,  $\alpha$  and  $\epsilon$  as well as  $\kappa$  and  $\lambda$  light chains. The C-Ig was always of the same isotype as the S-Ig detected on the corresponding freshly separated blood cells, whereas irrelevant

CLL cells, as reflected by heavy-chain ( $\mu$ ) variations. On average 5.5% of the fresh CLL cells contained cytophotometrically detectable amounts of C-Ig, and the proportion of such cells increased only slightly in the control cultures during 4 days. However, in cultures containing TPA there was a rapid increase in the percentage of C-Ig-positive lymphoid cells from (on average) 49% after 1 day to 92% after 3–4 days of culture. The relative amount of  $\mu$  chains increased two- to ninefold in TPA-treated CLL cells as compared with untreated cells. Under the influence of TPA, the S-Ig of CLL cells behaved reciprocally, as the proportion of S- $\mu$  chain-positive cells decreased from (on average) 90 to 9% together with a decrease in fluorescence intensity. However, a slight to moderate reduction in the percentage of S- $\mu$  chain-positive cells was also seen in untreated control cultures (Table 1).

The poor *in vitro* proliferative response of CLL cells to various mitogens<sup>16–18</sup> has previously led to the conclusion that CLL represents a clonal expansion of malignant B-lymphoid cells arrested at the stage of differentiation roughly corresponding to that of small resting lymphocytes. However, Fu and colleagues<sup>19</sup> recently studied two CLL patients expressing monoclonal serum Ig components idiotypically identical with the S-Ig of the CLL cells. When assisted by allogeneic helper T cells or Epstein-Barr virus (EBV), a fraction of the CLL cells matured into monoclonal, Ig-secreting plasma cells. A variable *in vitro* differentiation can also be induced in some ordinary CLL tumour populations using polyclonal B/T lymphocyte activators or EBV<sup>20</sup>.

The present study demonstrated that TPA, which has been previously found to be effective in inducing differentiation of mouse<sup>7</sup> and human<sup>7–11</sup> myeloid and monocytic<sup>12</sup> malignant cells, also effects CLL cells. The sequence of changes in the immunoglobulin expression and the ultrastructure of TPA-treated CLL cells is similar to that observed during differentiation of normal B cells. It is, therefore, possible that TPA-induced differentiation of CLL cells may be a useful model for human B-cell differentiation *in vitro*. In contrast to the EBV- or mitogen-induced differentiation, TPA seems to affect the whole tumour cell population, as more than 90% of the CLL cells changed both morphologically and with respect to C- and S-Ig expression. A second difference between EBV/mitogen and TPA as differentiation inducers in CLL cells seems to be that differentiation with TPA is associated with concomitant inhibition of DNA synthesis, as suggested by preliminary thymidine incorporation studies. Biosynthetic studies with TPA-induced CLL cells using a plaque assay and immunoprecipitation<sup>21</sup> indicate a cytoplasmic accumulation but only a minimal secretion of monoclonal immunoglobulin. Possibly the B cells do not reach the degree of maturation necessary for substantial immunoglobulin secretion. Alternatively, TPA may block secretion perhaps as a result of the inhibition of DNA synthesis.

Received 14 April; accepted 22 September 1980.

**Fig. 4** TPA-induced ultrastructural maturation of CLL cells. Lymphocytes cultured for three days in the absence (a) and presence (b) of TPA ( $\times 18,500$ ). Note the increase in the number of mitochondria, the amount of endoplasmic reticulum and the higher cytoplasmic:nuclear ratio in the TPA-treated cells.

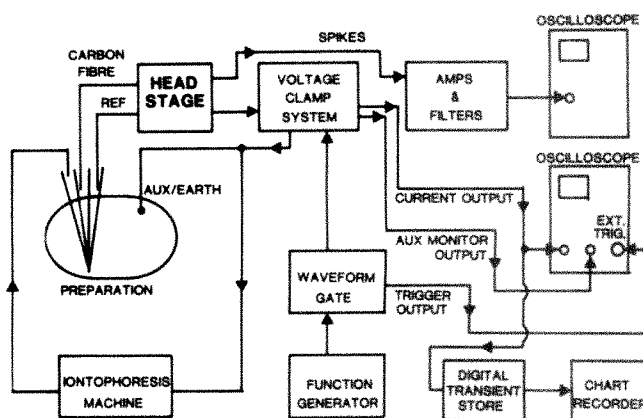

antisera stained only 0–1% of the cells weakly (data not shown). Therefore, TPA clearly induced the tumour cell population and not merely contaminating normal cells in these experiments. The TPA-induced ultrastructural changes in CLL cells (Fig. 4) consisted of an increased cytoplasmic:nuclear ratio together with increased amounts of mitochondria, endoplasmic reticulum and Golgi structures.

Table 1 shows the time-dependent TPA-induced changes in the expression and amounts of monoclonal C-Ig and S-Ig of

**Fig. 1** A block diagram of the apparatus used for spike recording and high-speed polarography. Switches are incorporated in the headstage and voltage-clamp systems. For extracellular single-unit (spike) recording, the signal from the carbon fibre-containing microelectrode barrel (CARBON FIBRE) is switched into a low-noise voltage follower in the headstage and then amplified and filtered in a conventional way. The auxiliary electrode (AUX/EARTH) is switched to ground. For polarography, a triangular waveform (see Fig. 2a) is obtained from a function generator and a waveform gate. This is fed into the preparation using the auxiliary electrode. The voltage at the tip of the microelectrode is monitored by the reference barrel (REF) and via a voltage-clamp system makes the voltage at the tip exactly follow the applied waveform. The current flow to ground through the carbon fibre caused by this voltage pattern is displayed on an oscilloscope, and may be output to a chart recorder through a digital transient store. A second channel of the oscilloscope monitors the voltage appearing at the auxiliary electrode.

Several problems are encountered when iontophoresis<sup>1,2</sup> is used to study the effects of putative neurotransmitters. The most significant is that it is not usually practical to estimate the concentration of drug obtained at the tip of the microelectrode by a current of a given strength. The usual methods, albeit rarely used, include measurement of transport numbers<sup>3,4</sup>, the use of ion-sensitive microelectrodes<sup>5,6</sup> and quantitative fluorescent microscopy<sup>7</sup>. With the exception of the ion-sensitive microelectrodes developed for acetylcholine<sup>5</sup>, these techniques are elaborate and time consuming, and cannot be routinely applied to every electrode used. Furthermore, conventional multibarrel microelectrodes have high-impedance recording barrels and thus often display low signal-to-noise ratios when recording single-cell activity, the noise being increased during iontophoresis. We describe here a technique which largely overcomes the problem of low spike signal-to-noise ratio in conventional multibarrel electrodes, and which, unlike the latter, also allows precise determination of the concentration of noradrenaline in the environment of the cell, which affects its excitability. The recording and iontophoretic properties of these electrodes have been described previously<sup>8</sup>. The use of these electrodes to quantify precisely iontophored noradrenaline by adapting polarographic techniques is described.

The high-speed polarographic technique was developed from systems being used for evaluating catecholamine levels in the central nervous system<sup>9,10</sup>. Our system differs principally in that it is some hundreds of times faster, is carried out at the single-cell, rather than macrocellular, level, and combines iontophoresis and single-cell recording. Full details of the methodology will be presented elsewhere; however, the principal features and a block diagram of the system (Fig. 1) are described here.

Three barrel microelectrodes were constructed in which one barrel contained a carbon fibre (outer diameter 7-8  $\mu\text{m}$ ), protruding 15  $\mu\text{m}$  from the glass, and etched to a 1- $\mu\text{m}$  point<sup>11,12</sup>. The other two (fluid-filled) barrels had outside diameters of 2-3  $\mu\text{m}$ . The carbon fibre electrode was connected via saline solution in the stem of the pipette to a current-to-voltage 'virtual-ground' field effect transistor (FET) operational amplifier. One other (reference) barrel was filled with 2 M NaCl, and connected to a voltage-follower FET. The third barrel was

filled with 0.1 M noradrenaline (NA) in dilute HCl ( $\text{pH} \sim 2$ ) for iontophoresis.

For *in vitro* calibration, the electrode tip was lowered into a beaker of 0.9% NaCl. Also dipping into the saline was a chlorided silver wire (the auxiliary electrode). The reference electrode was connected in a negative feedback loop with the auxiliary electrode, such that the auxiliary electrode would supply current to force the potential at the tip of the carbon microelectrode (monitored by the reference electrode) to follow any desired input voltage pattern. The current flow through the carbon fibre caused by these voltage changes was measured and displayed on an oscilloscope and printed out on a chart recorder via a digital transient store. A triphasic triangular waveform was used as the input voltage pattern. It was obtained by gating the output of a function generator. This waveform had a peak voltage of  $\pm 0.7$  V, a duration of 15 ms and was repeated twice per second (Fig. 2a). The precise current flow in the carbon electrode caused by this voltage pattern was determined by the impedance of the electrode-saline system<sup>11</sup>, and varied slightly from electrode to electrode, but was always similar to that shown in Fig. 2b.

When NA was added to the saline in the beaker, electro-oxidation of the amine occurred during the part of the cycle when the carbon fibre was anodic, according to the formula

It is generally accepted that the electrons liberated are taken into the working electrode (carbon fibre) and cause an increase in anodic current, and that subsequent reversal of potential causes a reduction of the quinone product back to NA, producing a corresponding increase in cathodic current<sup>9</sup>. Figure 2c

**Fig. 2** Polarographic currents recorded with carbon fibre microelectrodes. *a*, The voltage pattern applied to the carbon fibre tip of the microelectrode; *b*, shows the resultant current flow through the carbon fibre produced by this voltage pattern, when the microelectrode tip was immersed in 0.9% saline in a beaker; *c* shows a set of nine such polarographic current sweeps from a microelectrode in saline and eight different concentrations of NA in saline. The concentrations were  $2.8 \times 10^{-4}$  M for the largest trace, and then  $1.4 \times 10^{-4}$  M, 7, 5, 3, 2 and  $1 \times 10^{-5}$  M, and finally  $5 \times 10^{-6}$  M, for the second-smallest trace. The 'peak incremental current' for each concentration was measured at the time marked by the filled triangle. This was the extra current over the saline current caused by the oxidation of NA. *d* shows a set of current sweeps obtained with the microelectrode in saline using nine different levels of iontophoretic eject (tip positive) current through the NA-containing barrel of the microelectrode. They were 0, 10, 20, 40, 60, 80 and 120 nA. Scale in *a* applies only to *a*; scale in *d* applies to *b*, *c* and *d*.

The similarity between Fig. 2c and d is apparent. From the data in Fig. 2c, a calibration curve was constructed relating peak incremental current (measured at the points indicated by filled triangles) to the molar concentration of NA. From this curve and the data in Fig. 2d, a second curve relating iontophoretic eject current to tip concentration of NA in steady-state conditions could be produced. This curve is shown in Fig. 3.

For *in vivo* studies, the electrode was inserted into the primary somato-sensory cortex of urethane-anaesthetized rats. The auxiliary electrode was pushed into the retracted neck muscle. Figure 4 illustrates *in vitro* and *in vivo* data taken from another microelectrode. Figure 4a shows a set of current sweeps taken in different concentrations of NA in saline, ranging from  $10^{-5}$  to  $2 \times 10^{-3}$  M NA. Figure 4b shows current sweeps during iontophoresis in saline at different currents ranging from 20-nA retain to 100-nA eject. Figure 4c shows two sweeps with 20-nA retain, one in saline and the other *in vivo* (1,000- $\mu$ m down in the rat cortex). Apart from a slight increase in cathodic current *in vivo*, the sweeps are identical. Finally, Fig. 4d shows a set of current sweeps *in vivo* using the same iontophoretic eject currents as in Fig. 4b, taken after 60 s of iontophoretic eject current for each sweep. The catecholamine signals can be seen to be bigger *in vivo* than *in vitro*, presumably due to restricted diffusion of NA *in vivo*. In other cases, *in vivo* NA levels were less than *in vitro* ones, or fluctuated from second to second despite steady iontophoretic ejection, possibly reflecting variations in active noradrenergic uptake. Anyway, the signal shows the moment-to-moment variation in catecholamine levels at the investigated cell.

By switching the auxiliary electrode connection to ground and the carbon fibre electrodes into a low-noise voltage follower, extracellular voltage spikes were recorded from the investigated cortical neurone. The response of such neurones to iontophoretic NA was complex and will be reported elsewhere. Used as recording microelectrodes, carbon fibres had significantly lower noise than micropipettes and could distinguish axon and soma-dendrite spikes by waveshape<sup>8,13,14</sup>.

The technique of high-speed polarography using carbon fibre microelectrodes should have wide application in the study of the neurobiology of electroactive neurotransmitters. The method combines three techniques at the single-cell level—iontophoresis, recording of unit activity changes elicited by the

shows polarographic current sweeps in a series of different NA concentrations. Increasing concentrations of NA produced progressively increasing increments on the sweep at the peaks of oxidation and reduction. The reason for using a fast-gated triangular waveform was that this voltage pattern minimized build-up of reaction product and consequent poisoning of the electrode.

These experiments were done with a 'retain' (tip negative) iontophoretic current on the NA barrel. By reducing the retain current to zero, it was found that most of the NA-containing iontophoresis barrels showed appreciable 'leak' or passive diffusion of NA. By applying polarographic current sweeps at 2–10 Hz during iontophoretic eject currents of various levels, one could measure the concentrations of NA at the electrode tip. To establish adequate retain current, retain current was increased during polarographic pulses at 2 Hz. When the catecholamine signal disappeared, and further increase in retain current gave no change in signal, the retain current was considered adequate. For establishing steady levels of iontophoretically ejected catecholamine, we waited until the level of catecholamine signal maximally stabilized at a constant iontophoretic current. This 'lag time' varied in different electrodes and will be reported elsewhere. Signals from successive sweeps in these conditions invariably showed no detectable variations in amplitude, even when iontophoresis was continued for up to 30 min. Longer periods were not investigated.

Figure 2d shows a set of current sweeps made during NA iontophoresis using several different levels of ejection current.

**Fig. 3** Calibration curve relating the concentration of NA present at the tip of a multibarrel microelectrode immersed in saline to the level of steady iontophoretic ejection current through a NA-containing barrel. (The curve is constructed from data shown in Fig. 2c, d).

## Differential expression of H-2 gene products in tumour cells is associated with their metastatogenic properties

Patrick De Baetselier, Shulamit Katzav, Eliezer Gorelik, Michael Feldman & Shraga Segal

Department of Cell Biology, The Weizmann Institute of Science, Rehovot, Israel

Many neoplasms seem to be heterogeneous in nature<sup>1,2</sup>, producing metastases by pre-existing variant cells<sup>3,4</sup> with inherent biochemical and biological properties. The survival and proliferation of metastatic cells depend on various biological properties, such as enzymes which degrade basement membranes<sup>5</sup>, resistance to various host defence systems<sup>6,7</sup>, association with host cellular components<sup>8</sup>, adhesiveness<sup>9</sup> and expression of certain membrane glycoproteins<sup>10,11</sup>. Recent studies have indicated that metastatic cells may differ from the local tumour cells in the expression of immune recognizable membrane-associated antigens<sup>12,13</sup>. Such antigenic differences may result from an immunoselection of cells with distinct antigenic properties due to a specific immune response evoked against the local tumour. In view of the role of the major histocompatibility complex (MHC) system in controlling and restricting the function of immune effector cells against modified self-components<sup>14,15</sup>, one could assume that the modulation of the expression of MHC-encoded antigens on the membrane of tumour cells influenced the interclonal relationship within a local heterogeneous tumour cell population and the subsequent generation of metastasis. The modulation of the expression of H-2 antigens on several murine tumours is well documented<sup>16,17</sup>; however, practically no attempts were made to relate H-2 modulation with invasiveness. We now describe principal differences in the expression of H-2 parental haplotypes between a local F<sub>1</sub> methylcholanthrene-induced tumour and its descendant pulmonary metastases. These results suggest that both the expression and the immunogenicity of MHC products strongly influence the immune relationship between the tumour and the host's immune system, thus determining the generation and dissemination of metastases.

Mouse (T10) methylcholanthrene-induced sarcoma cells were serially transferred in syngeneic (C3HeB×C57BL/6)F<sub>1</sub> mice (H-2<sup>b</sup>×H-2<sup>k</sup>). Animals carrying subcutaneous solid T10 tumours regularly show the appearance of metastatic nodules in the lungs<sup>18</sup>. Because we intended to probe quantitative and qualitative differences in the membrane expression of murine MHC-encoded antigens on the local tumour and its metastatic descendants, local T10 (L-T10) and metastatic T10 (M-T10) cells were analysed for the membrane expression of both parental H-2<sup>b</sup> and H-2<sup>k</sup> haplotypes. The membrane expression of H-2 antigens was analysed using fluorescence serology carried out with the fluorescence-activated cell sorter (FACS-II). The use of the FACS allowed us to screen only for cells expressing high density of the relevant H-2 antigen. Such cells will be referred to as brightly stained cells. Solid tumours originating from subcutaneous transplants of L-T10 or M-T10 cells in (C3HeB×C57BL/6)F<sub>1</sub> mice were trypsinized and single-cell suspensions analysed for the relative number of cells stained either with anti-H-2<sup>k</sup> or with anti-H-2<sup>b</sup> antisera. From the comparison of the relative number of tumour cells expressing H-2<sup>b</sup> and H-2<sup>k</sup> antigens (data outlined in Table 1) and of the fluorescence distribution of M-T10 and L-T10 cells stained with either anti-H-2<sup>b</sup> or anti-H-2<sup>k</sup> antisera (Fig. 1), a clearcut difference was observed in the membrane expression of the parental H-2 haplotype on L-T10 compared with M-T10 cells. The data suggest that L-T10 cells express mainly or exclusively the H-2<sup>b</sup> parental haplotype whereas M-T10 cells express both the H-2<sup>b</sup> haplotype (although at a lower level than L-T10 cells)

Fig. 1 Fluorescence distribution of L-T10 and M-T10 cells stained with anti-H-2<sup>k</sup> or anti-H-2<sup>b</sup> antisera. The same staining conditions were used as described in Table 1 legend.

and the H-2<sup>k</sup> haplotype. These differential characteristics in H-2 expression were stable despite several serial transfers. In addition, different M-T10 clones (obtained from single metastatic nodules) showed identical staining patterns, implying the homogeneous nature of this variant. The H-2<sup>k</sup>-encoded molecules expressed on the M-T10 cells consisted of the serological determinants encoded by the different subregions, as the M-T10 cells were stainable with anti-H-2<sup>k</sup> antisera directed against both the H-2D and H-2K end products of the H-2<sup>k</sup> haplotype (Table 1). Again, L-T10 tumour cells were found to be serologically negative when analysed with these specific antisera. To test whether the M-T10 cells were pre-existing variants in the local tumour population, the L-T10 tumour cells were cloned in semi-solid agar, and individual clones which were passaged in F<sub>1</sub> recipients were analysed for the presence of H-2<sup>k</sup> or H-2<sup>b</sup>

Fig. 2 The capacity of L-T10 and M-T10 tumour cells to grow in parental hosts. 10<sup>6</sup> L-T10 or M-T10 cells were inoculated into the hind footpad of normal C57BL/6 or C3H/eb mice. At the indicated time intervals, the mean tumour diameter was recorded. Each group consisted of 10 mice.

membrane antigens. As shown in Table 2, the fluorescence analyses of 10 randomly chosen T10 clones revealed the presence of two clones (that is, IE7 and IB9) expressing both the H-2<sup>k</sup> and the H-2<sup>b</sup> parental haplotypes. The remaining clones were found to be H-2<sup>k</sup> negative but H-2<sup>b</sup> positive.

These last findings suggest that the original local T10 tumour consisted of a mixture of H-2<sup>k</sup>-positive and H-2<sup>k</sup>-negative cells, with a predominance of H-2<sup>k</sup>-negative cells. To approach the question of whether the H-2<sup>k</sup>-positive T10 tumour cells were identical in nature to the M-T10 cells, the capacity of the different L-T10 clones to produce lung metastases was tested by injecting 10<sup>6</sup> viable tumour cells intravenously (i.v.) and 2 weeks later examining the organs for the appearance of tumour nodules. The data outlined in Table 2 clearly indicate that the H-2<sup>k</sup>-positive clones are potentially able to survive in the peripheral blood stream and to develop subsequently in one organ, the lungs. No such features were observed with the H-2<sup>k</sup>-negative clones. These two concomitant characteristics—membrane expression of the H-2<sup>k</sup> parental haplotype and homing to the lung tissue—were stable, remaining unchanged even after 10 serial passages in syngeneic F<sub>1</sub> mice.

Additional evidence for the ability of H-2<sup>k</sup>-positive T10 tumour cells to circumvent the host's resistance mechanisms was obtained by analysing the growth capacities of L-T10 and M-T10 cells in parental recipients. When 10<sup>6</sup> viable L-T10 cells or M-T10 cells were grafted intra footpad to C57BL/6 (H-2<sup>b</sup>) mice or C3H/eb (H-2<sup>k</sup>) mice, differential growth patterns were observed, depending on the origin of the T10 tumour cells (Fig. 2). M-T10 cells were found to grow both in an H-2<sup>b</sup> and in an H-2<sup>k</sup> environment, whereas L-T10 cells grew only in H-2<sup>b</sup> mice

**Table 1** Parental H-2 haplotype expression on L-T10 and M-T10 tumour cells

The T10 sarcoma tumours from the original local tumour (L-T10) or from different metastatic pulmonary nodules (M-T10<sub>1,2,3</sub>) were maintained by subcutaneous transfers of 1 × 10<sup>6</sup> viable cells in (C3HeB × C57BL/6)F<sub>1</sub> mice. Single cell suspensions from solid tumours were prepared by treatment of minced tumour tissue with a solution of 0.3% trypsin (hog pancreas; Nutritional Biochemicals). The fluorescence stainings of the L-T10 and M-T10 tumour cells were performed using the following experimental protocol: 0.1 ml cells (3 × 10<sup>7</sup> cells ml<sup>-1</sup>) in Dulbecco's balanced salt solution with 0.02% NaN<sub>3</sub> (DBSS) were incubated with 0.01 ml antiserum (optimal concentration) at 4 °C during 30 min followed by two washings with DBSS. After resuspension in 0.1 ml DBSS, 0.010 ml of an optimal dilution of fluorescein-labelled rabbit anti-mouse Ig (Nordic Immunological Laboratory) was added and the cells were incubated for 20 min at 4 °C. After two washings with DBSS, the cells were analysed on the FACS-II (Becton-Dickinson). A scatter window was set to eliminate dead cells and cell debris. The frequency and fluorescence profile of the stained cells were determined using a laser output of 400 mW, photomultiplier at 450 V and fluorescent gain 4. The anti-H-2 antisera were obtained using the following immunization protocol: C3H.SW (H-2<sup>b</sup>) or C3H.DiSn (H-2<sup>k</sup>) were immunized intraperitoneally with 10<sup>8</sup> spleen cells of either C3H.DiSn or C3H.SW, respectively, weekly, for 4 weeks. Five days after the last injection the mice were bled and the obtained antisera checked for specificity using spleen cells and hydrocortisone-resistant thymocytes of different H-2<sup>k</sup> or H-2<sup>b</sup> congenic strains. The staining experiments outlined here were repeated on three successive serial transfers of L-T10 and M-T10 tumour cells (expts 1–3).

**Table 2** Parental H-2 haplotype expression and metastatic potential of T10 clones

| Expt no. | Tumour cells (origin) | Relative no. of cells stained with |                       | Presence of nodules in lung | Experimental metastases after i.v. inoculation |

T-10 cells were cloned in soft agar as previously described<sup>20</sup>. Briefly, tumour cells were seeded in soft agar medium (0.3%) on a harder agar (0.5%) medium supplemented with 15% FCS. After 10–14 days of incubation colonies were picked, expanded in liquid medium and transplanted subcutaneously into syngeneic F<sub>1</sub> mice. Single cell suspensions obtained after trypsin treatment of the different T10 tumours were analysed for the expression of H-2 antigens and for the capacity to form experimental metastases. The fluorescent stainings with anti-H-2<sup>b</sup> and anti-H-2<sup>k</sup> antisera on L-T10 tumour cells and different T10 clones were performed as described in Table 1 legend. The metastatic potential of different T10 clones was assessed by injecting 10<sup>6</sup> cells i.v. and 2–3 weeks later mice were killed and examined macroscopically for evidence of metastases to the lungs (—, no metastases; ±, <10 nodules, +, +, +, extensive involvement by tumour, numerous metastases). The level of infiltration was estimated by weighing the lungs (weight of normal lung = ±200 mg). The membrane expression of the parental H-2 haplotypes and the metastatic potential were repeated on some of the T10 clones obtained after different serial transfers (expt 1 = first transfer, expt 2 = 5th transfer; expt 3 = 10th transfer). ND, not done.

and were completely rejected in H-2<sup>k</sup> mice. This result suggests that the presence of H-2<sup>k</sup> antigens on the surface of T10 tumour cells somehow impairs semialloantigenic recognition.

Using a methylcholanthrene-induced tumour in (DBA/2 × A)/F<sub>1</sub> mice (MDAY), Kerbel *et al.*<sup>19</sup> recently reported that serial transfers of MDAY tumour cells through the parental DBA/2 mice led to the selection or formation of a putative H-2K<sup>k</sup> loss variant, with highly metastatic characteristics. This finding and our present results may suggest that the modulation in the expression of MHC products generates in certain instances neoplastic cells with higher ability to resist immune destruction, resulting in increased survival in the peripheral blood, before seeding in distant anatomical locations.

We thank Dr R. N. Apte for his help and expertise in isolating the T10-derived clones, Dr D. Meruelo for anti-H-2 antisera, and Mr Ezra Vaday and Ms Ziona Frenkel for technical assistance. The work was supported by the NCI under contract no. CB-74185. P.D.B. is a EURATOM and EMBO postdoctoral fellow.

iontophored substance and accurate measurement of the concentration of the iontophored substance. The sensitivity of the technique allows concentrations of  $5 \times 10^{-8}$  M NA and dopamine to be distinguished from background signal<sup>15</sup>. In comparison, other polarographic techniques<sup>10,16,17</sup> do not have the facility for iontophoresis, unit activity recording or electrode calibration *in vitro* before use *in vivo*. Finally, the time course of this polarographic recording technique (15 ms) approaches the time courses encountered during changes in neuronal activity in the nervous system. By using suitable high-speed switching between recordings of unit spike activity and polarographic measurement of catecholamine concentration, studies of the time course of responses in relation to known concentrations of drug in the central nervous system, which has previously been impossible, should now become feasible.

## Vitamin E modulates the lipoxygenation of arachidonic acid in leukocytes

Edward J. Goetzl

Howard Hughes Medical Institute Laboratory at Harvard Medical School, and the Departments of Medicine, Harvard Medical School and the Brigham and Women's Hospital, Boston, Massachusetts 02115

The arachidonic acid released from cellular phospholipids of specifically stimulated platelets and leukocytes is oxygenated enzymatically by two major pathways<sup>1-5</sup>. A complex cyclo-oxygenase converts some of the free arachidonic acid to labile endoperoxides that are transformed to prostaglandins, thromboxanes and prostacyclin (PGI<sub>2</sub>). Lipoxygenases convert part of the arachidonic acid to unstable hydroperoxy-eicosatetraenoic acids (OOHETEs) that are transformed to monohydroxy-eicosatetraenoic acids (HETEs), oligohydroxy-eicosatetraenoic or -eicosatrienoic acids such as di-HETEs and tri-HETEs, and, in some instances, more complex humoral mediators, including slow-reacting substances<sup>5-9</sup>. Both the nature of the HETEs and the ratio of the HETEs to the cyclo-oxygenase products are specific characteristics of each type of cell<sup>12,5</sup>. In human neutrophils, the sum of the lipoxygenase products 5-HETE, 11-HETE and 5,12-di-HETE substantially exceeds the total amount of PGE<sub>2</sub> and other cyclo-oxygenase metabolites that are generated concurrently<sup>3,4</sup>, and the endogenous lipoxygenase products regulate neutrophil function. The present data indicate that vitamin E ( $\alpha$ -tocopherol) bidirectionally modulates the activity of the lipoxygenase pathway of human neutrophils *in vitro*. Normal plasma concentrations of  $\alpha$ -tocopherol enhance the lipoxygenation of arachidonic acid, whereas higher concentrations of  $\alpha$ -tocopherol exert a suppressive effect that is consistent with its role as a hydroperoxide scavenger.

As extracellular mediators, the HETEs stimulate polymorphonuclear leukocyte random and chemotactic migration<sup>10-12</sup>, enhance the expression of C3b receptors<sup>12</sup> and increase the intra-leukocyte concentration of cyclic GMP (ref. 13). As the bulk of HETEs generated by human neutrophils and eosinophils is retained in the cellular membranes, whereas the PGE<sub>2</sub> produced is secreted, it has been suggested that the HETEs are functionally critical intracellular constituents<sup>14,15</sup>. In support of this, preincubation of neutrophils or eosinophils for 30-60 min with specific lipoxygenase inhibitors (for example, nordihydroguaiaric acid (5  $\mu$ M)) was observed to result in both significant depletion of cellular HETEs and suppression of random and chemotactic migration. The suppression of migration was reversed by the addition of purified exogenous HETEs to neutrophils and eosinophils deficient in endogenous HETEs as a result of pretreatment with lipoxygenase inhibitors<sup>14,15</sup>.

The levels of endogenous HETEs in neutrophils not stimulated by a chemotactic factor were enhanced a mean of two- to threefold by preincubation for 20 min at 37°C with 0.03-0.12 mM  $\alpha$ -tocopherol and were suppressed substantially by 0.5-1 mM  $\alpha$ -tocopherol ( $n = 3$ ). Neutrophils incubated with a chemotactic concentration of C5a exhibited mean increases of 2-, 1.5- and 2.5-fold, respectively, in the intracellular content of 5-HETE, 11-HETE and 5,12-di-HETE ( $n = 4$ ), and  $\alpha$ -tocopherol similarly modulated the enhanced level of HETEs in a concentration-dependent manner. In each instance, the increases and decreases were greatest for 5-HETE, whereas those of 5,12-di-HETE proved to be most resistant to suppression by 0.5-1 mM  $\alpha$ -tocopherol. The quantities of HETEs in the extracellular fluid were consistently less than 20% of those in the neutrophils, but the alterations elicited by  $\alpha$ -tocopherol paralleled those in the corresponding neutrophil pellets. To establish that the mechanism of action of  $\alpha$ -tocopherol was not a function of changes in the rate of mobilization of arachidonic acid from

**Fig. 1** Effects of  $\alpha$ -tocopherol on the lipoxygenation of exogenous arachidonic acid by human neutrophils. Portions of  $1 \times 10^8$  purified neutrophils were preincubated in 6 ml of Hanks' solution/0.1% ovalbumin (w/v), without or with various concentrations of highly purified  $\alpha$ -tocopherol (Supelco) for 20 min at 37 °C. Neutrophils were then washed twice, resuspended in 6 ml of the corresponding buffer without or with the same concentration of  $\alpha$ -tocopherol and incubated for 15 min at 37 °C with 160  $\mu$ g of arachidonic acid and 100  $\mu$ l of buffer (left-hand frame) or 100  $\mu$ l of the purified 15,000-molecular weight chemotactic fragment of the fifth component of complement, designated C5a (right-hand frame)<sup>12-15</sup>. The neutrophils were sedimented at 100g and the supernatant and neutrophil pellet, which had been resuspended in 6 ml of Hanks' solution and sonicated, were acidified to pH 4 with 2 M citric acid. After the addition of 40,000 c.p.m. of  $^3$ H-12-L-HETE<sup>14,15</sup> to each sample, the HETEs were extracted from each supernatant and sonicated with two 6-ml portions of chloroform/methanol (2:1, v:v) and two 3-ml portions of ether. The HETEs in the pooled extracts were separated from  $\alpha$ -tocopherol, resolved and purified by sequential silicic acid chromatography and reversed-phase HPLC<sup>14,15</sup> and quantified by optical density at 235 nm (mono-HETEs) or 280 nm (5,12-di-HETE) with a correction for recovery according to the yield of  $^3$ H-12-L-HETE. The range of intracellular content of 5-HETE, 11-HETE and 5,12-di-HETE in control neutrophils (100%) was 3,711–5,841, 1,833–3,271 and 594–1,071 ng per  $10^8$  neutrophils, respectively, in buffer alone and 6,914–11,046, 3,774–5,650 and 1,468–2,348 ng per  $10^8$  neutrophils with C5a. Each data point and bar are the mean  $\pm$  s.d. for four experiments. The level of statistical significance of the difference between each value and the corresponding control value were determined by a standard two-sample *t*-test and are depicted by \*  $P < 0.01$  and †  $P < 0.05$ .

phospholipids, the studies were repeated using 160  $\mu$ g of exogenous arachidonic acid per  $10^8$  neutrophils, of which over 90% was taken up by the neutrophils to provide a quantity that exceeded by approximately twofold the total amount in the native cellular pool<sup>14,15</sup>. Although the introduction of exogenous arachidonic acid augmented the content of intracellular HETEs by nearly 10-fold, the bidirectional effects of  $\alpha$ -tocopherol (Fig. 1) were similar in magnitude to those elicited in the absence of exogenous arachidonic acid. The optimal increase in the content of each of the HETEs was evoked by 0.06 mM  $\alpha$ -tocopherol and maximal suppression was achieved by 1 mM  $\alpha$ -tocopherol.

As  $\alpha$ -tocopherol reacts specifically with OOH-groups, it was also anticipated that the generation by neutrophils of 5-OOHETE and other OOHETEs would be influenced by alterations in the cellular level of  $\alpha$ -tocopherol (Table 1). The ratio of the quantities of 5-OOHETE to 5-HETE was increased more than twofold by 0.03 mM  $\alpha$ -tocopherol and was suppressed to ~30% of control values by 0.5 mM  $\alpha$ -tocopherol in the absence of a specific agonist. Despite the 5.1-fold higher mean levels of 5-HETE in neutrophils exposed to the calcium ionophore A23187, the same concentrations of  $\alpha$ -tocopherol exerted effects on the ratio of 5-OOHETE to 5-HETE that were of similar magnitude to those observed for neutrophils in buffer (Table 1). Alterations by  $\alpha$ -tocopherol in the ratio of OOHETE to HETE secreted by neutrophils would influence the net

activity of any concentration of the lipid factors as extracellular mediators. 12-OOHETE and 5-OOHETE elicit maximal neutrophil chemotactic responses at 4  $\mu$ g ml<sup>-1</sup> and 0.4  $\mu$ g ml<sup>-1</sup>, respectively, that exceed by over 50% the maximal chemotactic responses to 10–20  $\mu$ g ml<sup>-1</sup> of 12-HETE and 1–2  $\mu$ g ml<sup>-1</sup> of 5-HETE<sup>10-13</sup>. Similarly, both OOHETEs are more active than the respective HETEs in evoking an optimal neutrophil chemokinetic response. Not only are the OOHETEs 10-fold more potent than the HETEs in augmenting the intra-neutrophil concentration of cyclic GMP, but also the elevation achieved lasts for 30 min or longer, compared with between 10 and 20 min for that achieved by the HETEs.

$\alpha$ -tocopherol modulates human neutrophil migration *in vitro* at concentrations that affect the lipoxygenase pathway. The preincubation of neutrophils with 0.06 mM  $\alpha$ -tocopherol for 20 min enhanced neutrophil random migration by 18–54% and chemotaxis to C5a by 29–106% ( $n = 3$ ), whereas 1 mM  $\alpha$ -tocopherol inhibited neutrophil random migration by 53–70% and chemotaxis by 32–56%, as assessed by a modified Boyden micropore filter assay<sup>12-15</sup>. The addition of nanogramme amounts of exogenous 5-HETE to  $2 \times 10^6$  neutrophils depleted of endogenous 5-HETE and 11-HETE by prior treatment with lipoxygenase inhibitors, such as nordihydroguaiaretic acid, completely reverses the defect in neutrophil migration that is characteristic of the HETE-depleted neutrophils<sup>14,15</sup>. Thus, it would be expected that the addition of 5-HETE to neutrophils preincubated in 1 mM  $\alpha$ -tocopherol would reverse the inhibition of migration, if the sole abnormality were a depletion of endogenous HETEs. Preincubation of neutrophils with 1 mM  $\alpha$ -tocopherol depleted the intracellular content of 5-HETE by a mean of 71% ( $n = 3$ ), suppressed the ratio of 5-OOHETE to 5-HETE from a mean of 0.18 to 0.10 and concurrently inhibited random migration by 64% and chemotaxis to C5a by 52%. In contrast to the results with lipoxygenase inhibitor-treated neutrophils, however, the addition of 0.2–2.5 ng 5-HETE without or with 10–200 ng 11-HETE to  $2 \times 10^6$   $\alpha$ -tocopherol-treated neutrophils failed to reverse the migration defects. The effects of  $\alpha$ -tocopherol on human neutrophil function thus are not solely attributable to alterations in the cellular content of endogenous HETEs, and may also reflect changes in the concentrations of OOHETEs or non-lipoxygenase-related actions of  $\alpha$ -tocopherol.

$\alpha$ -tocopherol serves an important role as 'biological antioxidant' by preventing the peroxidation of polyunsaturated fatty acid constituents of cellular membranes, including arachidonic

**Table 1** Modification of the ratio of 5-OOHETE to 5-HETE in human neutrophils by  $\alpha$ -tocopherol

| Concentration of $\alpha$ -tocopherol (mM) | Buffer           | A23187          |
|--|------------------|-----------------|
| 0  | 0.16 $\pm$ 0.04* | 0.17 $\pm$ 0.07 |
| 0.03                                       | 0.36 $\pm$ 0.12  | 0.32 $\pm$ 0.15 |
| 0.12                                       | 0.10 $\pm$ 0.06  | 0.12 $\pm$ 0.09 |
| 0.50                                       | 0.05 $\pm$ 0.01  | 0.08 $\pm$ 0.02 |

Portions of  $3 \times 10^8$  purified neutrophils were preincubated in buffer without or with  $\alpha$ -tocopherol, washed and resuspended in buffer of the same composition as described in Fig. 1 legend, with 160  $\mu$ g arachidonic acid per  $10^8$  neutrophils, and calcium ionophore A23187 at a final concentration of 5  $\mu$ M. After 10 min at 37 °C, the neutrophils were sedimented and the 5-OOHETE and 5-HETE extracted and purified as described in Fig. 1 legend. The ratio of 5-OOHETE to 5-HETE was determined by assessing the concentration of OOH-groups in the mixtures of the two compounds based on the conversion of triphenylphosphine to triphenylphosphine oxide and measurement of the quantity of triphenylphosphine oxide by gas-liquid chromatography<sup>27</sup>.

\* Each value is the mean  $\pm$  s.d. of the results from three separate experiments.

acid<sup>16-19</sup>. A deficiency of  $\alpha$ -tocopherol in rat or human neutrophils results in greater than normal release of hydrogen peroxide, augmented peroxidation of membrane lipids and impairment of chemotaxis and phagocytosis that are corrected rapidly by either the addition of  $\alpha$ -tocopherol *in vitro* or the prior administration of several doses of  $\alpha$ -tocopherol to the neutrophil donors<sup>20</sup>. Although the optimal cyclooxygenation of arachidonic acid to prostaglandins in rabbit tissues requires physiological concentrations of  $\alpha$ -tocopherol<sup>21,22</sup>, the mechanism of this apparent facilitation of oxidation by  $\alpha$ -tocopherol is unknown. The present data document for the first time the bidirectional modulation by  $\alpha$ -tocopherol of the lipoxygenation of arachidonic acid to products which serve as both specific extracellular mediators and functionally critical intracellular constituents. The generation of endogenous neutrophil 5-HETE, 11-HETE and 5,12-di-HETE was significantly enhanced *in vitro* by 0.03 mM and 0.06 mM  $\alpha$ -tocopherol, which approximate the normal human serum concentration of 0.01–0.05 mM (refs 23, 24). The neutrophil lipoxygenase pathway was inhibited significantly by levels of 0.25–1 mM  $\alpha$ -tocopherol, which increase the content of  $\alpha$ -tocopherol in platelets and leukocytes by up to 5–17-fold within 5 min of incubation *in vitro* and are obtainable *in vivo* by the ingestion of pharmacological doses of  $\alpha$ -tocopherol<sup>23,24</sup>. The mechanism of the enhancement of lipoxygenation of arachidonic acid in neutrophils by physiological levels of  $\alpha$ -tocopherol is not related simply to alterations either in the formation of lipid hydroperoxides or in the liberation of endogenous arachidonic acid from phospholipids. The demonstration that the function of some acetylcholine receptors in phospholipid liposomes is

optimal only when  $\alpha$ -tocopherol represents a substantial fraction of the total lipid content<sup>25</sup> and that  $\alpha$ -tocopherol is required for the incorporation of excitability-inducing material into black lipid membranes<sup>26</sup>, suggests that a normal content of  $\alpha$ -tocopherol in neutrophil membranes also may be required for maximal expression of lipoxygenase activity.

J. A. Swenberg\*

Department of Pathology, Chemical Industry Institute of Toxicology, Research Triangle Park, Durham, North Carolina 27709

Chronic administration of several chemical carcinogens to laboratory animals induces a variety of tumours which arise from specific cell populations within the liver. In the rat, diethylnitrosamine induces hepatocellular carcinomas<sup>1</sup>, dimethylnitrosamine induces both angiosarcomas<sup>2</sup> and hepatocellular carcinomas<sup>3</sup>, vinyl chloride primarily induces angiosarcomas<sup>4</sup>, and 1,2-dimethylhydrazine induces malignant haemangioendotheliomas<sup>5,6</sup>. One of the principal mechanisms thought to be involved in initiating carcinogenesis is the alkylation of specific sites on DNA, such as the  $O^6$  position of guanine<sup>7</sup>. Previous investigations of alkylation and repair have, however, analysed DNA prepared from whole liver. This approach does not localize alkylation or repair capacity in the different cell types which give rise to neoplasia. Furthermore, although hepatocytes account for more than 90% of the liver's mass, they only comprise 60–70% of its cells<sup>8</sup>. The nonparenchymal cell (NPC) population, which consists almost entirely of endothelial and Kupffer cells, accounts for the remaining 30–40% and contains 10–20% of the DNA. Therefore, we decided to investigate the alkylation and repair of  $O^6$ - and 7-methylguanine in the target and non-target cells following oral administration of 1,2-dimethylhydrazine. We report here that although initial alkylation was slightly less in NPCs, removal of  $O^6$ -methylguanine was significantly slower. This led to a preferential accumulation of  $O^6$ -methylguanine in NPC 24 h after administering a second daily dose. In contrast, 7-

methylguanine decreased at similar rates, resulting in a 28-fold greater  $O^6$ -methylguanine/7-methylguanine ratio in the target cell population.

Administration of 1,2-dimethylhydrazine (DMH) at a dose of 3 mg per kg per day in the drinking water induces a high incidence of tumours arising from the vascular lining cells of the liver in BDIX rats. Investigations of DMH-induced alkylation and repair in whole liver have demonstrated that maximal DNA alkylation occurs within 12 h for doses ranging from 4 to 20 mg per kg (refs 9, 10).  $O^6$ -Methylguanine is rapidly removed from DNA by an enzymatic process, whereas 7-methylguanine is lost at a slower rate by chemical depurination, leading to a decreasing  $O^6$ -/7-methylguanine ratio<sup>11</sup>. This pattern is similar to that observed after the administration of dimethyl- or diethylnitrosamine<sup>12</sup>. Nothing is known of the localization of methylated purines within the two major liver cell populations or the capacities of the different cells to repair  $O^6$ -methylguanine.

Previous attempts to separate NPCs from hepatocytes have used density gradient centrifugation<sup>13</sup> or the selective destruction of hepatocytes by pronase digestion<sup>14</sup>. Both these methods have serious limitations for use in a comparative study of alkylation and repair. When density gradient centrifugation is used, yields are inversely proportional to purity and many of the media used are hyperosmotic or mildly toxic. With pronase digestion, high yields of relatively pure NPCs can be obtained; however, destruction of the hepatocytes negates the possibility of studying two populations of cells from the same liver. In addition, the massive destruction of hepatocytes in the presence of the NPCs results in phagocytosis of hepatocellular debris by Kupffer cells<sup>8</sup>, possibly contaminating them with hepatocellular DNA. Elutriation centrifugation<sup>15</sup>, which separates mainly on the basis of cell volume, exploits the enormous difference between the volume of the hepatocyte and NPC<sup>8</sup>. This technique can be used to separate a mixed liver cell suspension derived from collagenase perfusion<sup>16</sup> into populations of NPCs and hepatocytes with a purity of 95% or greater. The NPC population consists almost entirely of Kupffer and endothelial cells<sup>17</sup>. Bile duct cells remain in the filter leavings during the preparation of the mixed liver cell suspension. Purity of the populations can easily be monitored by light microscopy due to

**Fig. 1** Separation of a mixed liver cell suspension (MLCS) (a) into hepatocytes (b) and NPCs (c) by elutriation centrifugation (haematoxylin and eosin stain for hepatocytes, Wrights stain for NPCs  $\times 400$ ). A MLCS was prepared as previously described<sup>16</sup> by *in situ* perfusion of the liver with collagenase through the portal vein. The resultant MLCS was washed three times in HBSS without  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  at  $4^\circ\text{C}$ . After washing, the cells were resuspended in 20 ml of HBSS without  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  and slowly injected into the large mixing chamber (70 ml) of the Beckman JE-6 elutriation rotor containing a Sanderson separation chamber in a Beckman J2-21 refrigerated centrifuge equipped with a fine speed control. The rotor speed was held constant at 1,500 r.p.m., and the media flow rate varied. The MLCS was washed into the rotor at a flow rate of  $18\text{ ml min}^{-1}$  until the separation chamber became approximately 50% full of retained hepatocytes. The flow of media was then diverted around the mixing chamber directly through the separation chamber and the retained hepatocytes washed until 200 ml of media containing the NPCs had been collected. The hepatocytes were then flushed from the rotor at a flow rate of  $100\text{ ml min}^{-1}$ . After the separation chamber was emptied the flow rate was returned to  $18\text{ ml min}^{-1}$  and the flow again routed through the mixing chamber washing in a second portion of the MLCS. This procedure was repeated four or five times until all the cells that could be washed from the mixing chamber had been separated. Yields varied from  $2\text{--}5 \times 10^6$  NPCs and  $6\text{--}11 \times 10^6$  hepatocytes per liver and were  $\geq 95\%$  pure as determined by counting on a haemocytometer. The absence of bile duct epithelium in the NPC and hepatocyte fractions was confirmed using  $\gamma$ -glutamyl transpeptidase enzyme histochemistry.

**Fig. 2** Representative radiochromatograms of hydrolysed DNA from NPCs (a) and hepatocytes (b) of a rat killed 24 h after two daily doses of  $^{14}\text{C}$ -DMH. DNA was extracted from the cell pellets by hydroxyapatite chromatography as previously described<sup>18</sup> and the purines liberated by mild acid hydrolysis ( $0.1\text{ M HCl}$  at  $80^\circ\text{C}$  for 30 min). After hydrolysis the solution was made  $0.01\text{ M NaPO}_4$ , the pH adjusted with  $1\text{ M NaOH}$  to 5.5, filtered and applied to a  $45 \times 0.9\text{-cm}$  glass column containing 20 g (dry weight) of ultra fine Sephasorb HP (Pharmacia). The column was eluted with  $0.01\text{ M NaPO}_4$  buffer pH 5.5 at a flow rate of  $1\text{ ml min}^{-1}$  (100 p.s.i.) using a Laboratory Data control HPLC pump. The concentrations of guanine and adenine were determined by integrating the area under the curve for their absorbance at 254 nm using a Shimadzu C-EIA integrator and a Uvicord S monitor. Samples of 3 ml were collected until the beginning of the guanine peak, after which 6-ml samples were collected. Two volumes of ACS scintillation fluid were added to each sample and they were counted for 10 min at a counting efficiency of 79% in a Searle mark III scintillation counter using channel 3. The concentrations of 7- and  $\text{O}^6$ -methylguanine were expressed as a fraction of guanine and were calculated assuming that the specific activity of the alkylation products was one-half that of the carcinogen because only one labelled methyl group is available for alkylation<sup>19</sup>.

the large difference in size and morphology (Fig. 1). An additional advantage of elutriation centrifugation is that it can be performed at  $4^\circ\text{C}$ .

To quantify differences in alkylation and repair and to test for possible accumulation of alkylation products, nine male BDIX rats weighing 150–200 g were given an oral dose of  $^{14}\text{C}$ -DMH (3 mg per kg, specific activity  $7.5\text{--}8.0\text{ }\mu\text{Ci mmol}^{-1}$ ). Three animals were killed at 2 and 24 h, their livers perfused and the cells separated and frozen. The remaining three animals received a second dose of  $^{14}\text{C}$ -DMH 24 h after the first dose, and were killed and their liver cells separated 24 h later. DNA from the different cell populations was purified by hydroxyapatite chromatography<sup>18</sup>, hydrolysed in  $0.1\text{ M HCl}$  at  $80^\circ\text{C}$  for 30 min and the purines separated by gel filtration chromatography (Fig. 2).

The extent of the initial alkylation was slightly less in NPCs than in hepatocytes 2 h after carcinogen administration (Table 1). In contrast, after 24 h only 10% ( $8.9 \pm 4.4\text{ pmol}$  of  $\text{O}^6$ -methylguanine per  $\mu\text{mol}$  of guanine) of the initial amount of  $\text{O}^6$ -methylguanine persisted in the hepatocytes, whereas 53%

† Not detectable.

‡ Second dose administered 24 h after the first dose.

( $34.6 \pm 1.1$  pmol of  $\text{O}^6$ -methylguanine per  $\mu\text{mol}$  of guanine) remained in the NPCs ( $P < 0.01$ , 1-tailed  $t$ -test). 7-Methylguanine decreased at a similar rate in the NPC (27%) and hepatocyte (30%) populations during the 24 h following oral administration of  $^{14}\text{C}$ -DMH.

With 53% of the initial  $\text{O}^6$ -methylguanine remaining in the NPCs, and assuming that previous and newly formed  $\text{O}^6$ -methylguanine are repaired at the same rate, the amount of  $\text{O}^6$ -methylguanine accumulating in the NPCs 24 h after a second dose of  $^{14}\text{C}$ -DMH was estimated to be 53 pmol of  $\text{O}^6$ -methylguanine per  $\mu\text{mol}$  of guanine. The observed value was  $56.3 \pm 4.3$  pmol  $\text{O}^6$ -methylguanine per  $\mu\text{mol}$  guanine. No accumulation of  $\text{O}^6$ -methylguanine was detected in the corresponding hepatocytes whereas, in contrast, 7-methylguanine accumulated in both populations (Table 1). An additional indication of the marked differences in the two cell populations' capacity for repair of  $\text{O}^6$ -methylguanine is demonstrated by comparing the  $\text{O}^6/7$ -methylguanine ratios. These ratios were similar at 2 h, 6 times higher in the NPCs at 24 h and 28 times higher in the NPCs 24 h after administration of the second dose of  $^{14}\text{C}$ -DMH (Table 1). As the 7-methylguanine was removed at a similar rate for both cell populations, the change in ratio clearly demonstrates that the hepatocytes were more efficient than the NPCs at removing  $\text{O}^6$ -methylguanine from their DNA.

An additional difference observed between the two cell populations was the incorporation of  $^{14}\text{C}$  from  $^{14}\text{C}$ -DMH into normal purine bases via the C-1 pool. Incorporation of  $^{14}\text{C}$  was much higher in the NPCs than the hepatocytes 24 h after the second dose of  $^{14}\text{C}$ -DMH (Table 1). The slower rate of DNA repair and increased amount of metabolic incorporation suggest that non-repair-related DNA synthesis, that is, cell replication, is occurring in the NPCs. This may be due to selective cytotoxicity for the NPCs leading to repopulation.

This present study demonstrates that different cell populations in the intact rat liver possess different capacities for DNA repair. It further shows that in DMH-induced carcinogenesis the target cell population (NPCs) accumulates the promutagenic alkylation product,  $\text{O}^6$ -methylguanine, whereas the non-target cell (hepatocyte) does not. It also suggests that the rate of cell division may be higher in the target cells. These data are consistent with the hypothesis that the extent of promutagenic DNA damage, the capacity to repair such damage, as well as the degree of cell replication represent critical events which correlate with carcinogenesis. Previous investigations of organ-specific carcinogenesis<sup>7,11</sup> have supported this conclusion; however, this is the first demonstration of cell specificity within the target organ.

We thank Ms Kathryn Caton Billings for technical assistance and Ms Mary Bedell and Dr Gerhard Doerjer for their thoughtful advice.

## L-leucine and a nonmetabolized analogue activate pancreatic islet glutamate dehydrogenase

Abdullah Sener & Willy J. Malaisse

Laboratory of Experimental Medicine, Brussels University, Brussels, Belgium B-1000

The release of insulin evoked by nutrients in the pancreatic  $\beta$ -cell is attributed to either the activation of a stereospecific receptor by the nutrient molecule itself or the generation of one or more signal(s) through the intracellular metabolism of the nutrient secretagogue<sup>1</sup>. The first of these hypotheses is apparently supported by the fact that nonmetabolized amino acids, especially the L-leucine analogue b(-)-2-amino-bicyclo[2, 2, 1]heptane-2-carboxylic acid (BCH), stimulate insulin release<sup>2</sup>. However, we now report evidence in support of the second hypothesis. We present data consistent with the idea that BCH induces insulin release through the allosteric activation of glutamate dehydrogenase. This is compatible with the fuel hypothesis, which states that the secretory response to nutrient secretagogues depends always on an increase of catabolic fluxes in the islet cells<sup>3,4</sup>.

The activity of glutamate dehydrogenase in islet homogenates was measured at pH 8.0 and 25 °C in the presence of  $\text{NH}_4^+$  50.0 mM,  $\alpha$ -ketoglutarate 7.0 mM and NADH 0.1 mM, as described elsewhere<sup>5</sup>. L-leucine and b(-)-BCH were equally potent in causing allosteric activation of the enzyme (Fig. 1). D-leucine had no effect on enzyme activity (data not shown). The velocity of the reaction catalysed by glutamate dehydrogenase was considerably increased by ADP (0.5 mM). Even in the presence of ADP, L-leucine and b( $\pm$ )BCH still caused a significant increase in reaction velocity (Fig. 1). L-norvaline and L-isoleucine also caused activation of glutamate dehydrogenase, although to a lesser extent than L-leucine (Table 1). Glycine,

The activity of glutamate dehydrogenase was measured in islet homogenates. Insulin release was measured in islets incubated in the absence or presence of L-glutamine. Mean values ( $\pm$  s.e.m.) are shown together with the number of individual determinations (in parentheses).

\* $P < 0.001$ ; † $P < 0.005$ ; ‡ $P < 0.02$ ; § $P < 0.05$ . The statistical indices refer either to the differences between basal (first line) and experimental values (first and second columns) or to the glutamine-induced increment in insulin output (third column).

L-serine, L-valine, L-norleucine and L-lysine failed to activate glutamate dehydrogenase. These results are virtually identical to those found in isolated rat liver mitochondria or with purified glutamate dehydrogenase extracted from bovine liver<sup>6–8</sup>.

The possible relevance of changes in enzyme activity to the secretory behaviour of the  $\beta$ -cell was investigated by examining the influence of L-glutamine (10 mM) on insulin release in islets exposed to various amino acids. This approach was motivated by the following considerations. First, in the islets, L-glutamine is extensively converted to glutamate and, hence, provides much larger amounts of substrate for glutamate dehydrogenase than exogenous glutamate, which is poorly transported into the islet cells<sup>9</sup>. Second, L-glutamine itself fails to affect insulin release by the islets, whether in the absence or presence of D-glucose<sup>9</sup>. Insulin release was measured in groups of eight islets each incubated for 90 min at 37 °C in a bicarbonate-buffered medium<sup>10</sup>.

As shown in Table 1, L-glutamine markedly enhanced insulin release provoked by L-leucine or b( $\pm$ )BCH, augmented

secretion to a lesser extent in the presence of L-norvaline or L-isoleucine, and failed significantly to increase insulin output in the presence of glycine, L-serine, L-valine, L-norleucine or L-lysine. There was a highly significant correlation ( $r = 0.9786$ ;  $P < 0.001$ ) between the magnitude of the glutamine-induced increment in insulin output in the presence of different amino acids and their capacity to activate glutamate dehydrogenase in islet homogenates. In contrast, the magnitude of the glutamine-induced increment in insulin output was not closely related to the capacity of a given amino acid to stimulate secretion in the absence of L-glutamine.

The dose-response relationship for the effect of L-leucine and L-glutamine on insulin release, as illustrated in Fig. 2, indicated that a dramatic augmentation of L-leucine-induced insulin release occurred in the presence of 1.0 mM L-glutamine, at a concentration close to physiological value. The threshold value for L-leucine-induced release (3.0–5.0 mM) was the same in the absence or presence of L-glutamine. However, at higher concentrations of L-leucine, the dose-response relationship was

**Fig. 1** Effect of L-leucine (open symbols) and b(-)BCH (assumed to represent half of the b( $\pm$ )BCH concentration effectively used; closed symbols) on the activity of glutamate dehydrogenase measured in islet homogenates in the presence (triangles) or absence (circles) of ADP (0.5 mM). Each value was measured in triplicate.

**Fig. 2** Mean values ( $\pm$  s.e.m.) for insulin release from pancreatic islets refer to 7–136 individual observations. Left panel: effect of increasing concentrations of L-leucine in the absence (solid line) or presence (dotted line) of L-glutamine (10.0 mM). Right panel: effect of increasing concentrations of L-glutamine in the absence (solid line) or presence (dotted line) of L-leucine (20.0 mM).

different in the presence and absence of L-glutamine, respectively. In the presence of L-glutamine, the secretory rate virtually reached a maximal value at a 10 mM concentration of L-leucine. In the absence of L-glutamine, even 20 mM L-leucine was not sufficient to evoke a maximal secretory response, the output of insulin being further increased when the concentration of L-leucine was raised to 40 mM (ref. 11). This difference in dose-response relationship may be explained as follows. In the presence of L-glutamine, the secretory response is largely dependent on the rate of glutamate metabolism, the catabolism of L-leucine itself being severely impaired (data not shown). Hence, a maximal secretory rate will be reached whenever the mitochondrial concentration of L-leucine (or  $b(\pm)$ BCH) is sufficient to cause full activation of glutamate dehydrogenase. In the absence of L-glutamine, however, the secretory response is largely dependent on the rate of L-leucine catabolism<sup>11</sup> and, hence, may require higher concentrations of this amino acid to reach its maximal value. This is not to deny that, in the absence of exogenous L-glutamine, the secretory response to L-leucine depends in part on the rate of endogenous glutamate metabolism, as activated by the branched-chain amino acid. In fact, the extent to which L-leucine, independently of its own catabolism, stimulates insulin release by facilitating the metabolism of glutamate derived from endogenous precursors can be judged from the effect of  $b(\pm)$ BCH on insulin release in the absence of exogenous L-glutamine (Table 1 and ref. 12).

Several findings suggest the existence of a causal link between activation of glutamate dehydrogenase and stimulation of insulin release. Thus, in addition to the above-mentioned correlation between enzyme activation by different amino acids and the magnitude of the glutamine-induced increment in insulin output, both the enzyme activation and secretory response<sup>12</sup> are stereospecific for the L-form of leucine. Moreover, detailed biochemical and functional studies performed in intact islets exposed to the combination of L-leucine and L-glutamine indicated that the secretory response to these amino acids is indeed linked to activation of the NAD(P)H-dependent enzyme glutamate dehydrogenase, and is associated with a more reduced state of cytosolic redox couples, abolished by menadione, and triggered by the cellular accumulation of calcium and subsequent activation of the  $\beta$ -cell microtubular-microfilamentous effector system (data not shown). These findings emphasize the essential role of reducing equivalents in the coupling between metabolic and cationic events in the process of nutrient-induced insulin release<sup>3</sup>.

In conclusion, the present data indicate that the capacity of a nonmetabolized amino acid to augment  $O_2$  consumption by the islets<sup>13</sup>, to increase their content in NAD(P)H (ref. 14), to provoke a phosphate flush<sup>15</sup> and to stimulate insulin release<sup>2</sup> is compatible with the fuel hypothesis for insulin release<sup>3</sup>.

The enzyme (2-5A synthetase) which synthesizes  $ppp(A_2'p)_nA$  where  $n = 2$  to 4 (collectively referred to as 2-5A)<sup>1</sup> is widely distributed in a variety of cells and tissues in amounts which increase in response to interferon<sup>2-5</sup> and vary with growth and hormone status<sup>6</sup>. 2-5A activates a nuclease which inhibits protein synthesis<sup>7-10</sup>. The non-phosphorylated 'core' of 2-5A ( $(A_2'p)_nA$ ,  $n = 2$  to 4) can inhibit DNA synthesis and cell growth<sup>11,12</sup>. Here we describe convenient and sensitive radioimmune (RI) and radiobinding (RB) assays for core and 2-5A. In combination with more satisfactory high performance liquid chromatography (HPLC) methods using reverse-phase C18 columns, these assays have been used to detect core and 2-5A in crude extracts from interferon-treated cells. The novel 2-5A synthetase products  $NAD_2'p_5'A_2'p_5'A$  and  $A_5'p_5'A_2'p_5'A_2'p_5'A$  (ref. 13), which can also be detected using the RB assay, were not found in significant amounts. The natural occurrence of core has not been described previously.

The RI and RB assays are based on the high affinities of core for antibody and of 2-5A for the 2-5A-dependent nuclease<sup>9,10</sup> respectively. In both cases the amount of <sup>32</sup>P-labelled core or 2-5A bound to antibody or nuclease is determined by its retention on nitrocellulose filters. The concentration of unknown samples is measured by the ability of suitable dilutions to

**Table 1** Specificity of the radioimmune and radiobinding assays

| Compound                          | Concentration for 50% displacement of probe* |
|-----------------------------------|--|
| <b>a, Radioimmune assay</b>       |  |
| $(A_2'p)_2A$ and $(A_2'p)_3A$     | 1 nM   |
| $p(A_2'p)_2A$                     | 5 nM   |
| $pp(A_2'p)_2A$                    | 100 nM                                       |
| $ppp(A_2'p)_2A$                   | 500 nM                                       |
| 2'- and 3'-AMP                    | 5 $\mu$ M                                    |
| 5'-AMP                            | 10 $\mu$ M                                   |
| $(A_3'p)_2A$ and $(A_3'p)_3A$     | 10 $\mu$ M                                   |
| $A_3'p_5'A$                       | 50 $\mu$ M                                   |
| Adenosine                         | 500 $\mu$ M                                  |
| ATP, CTP, pCp, 2'-, 3'- and 5'-   | >1 mM  |
| <b>CMP</b>                        |  |
| <b>b, Radiobinding assay</b>      |  |
| $ppp(A_2'p)_nA$ , ( $n = 2$ to 4) | 1 nM   |
| $pp(A_2'p)_2A$                    | 1 nM   |
| $p(A_2'p)_2A$                     | 7 nM   |
| $(A_2'p)_2A$                      | 300 nM                                       |
| $(A_3'p)_2A$ and $(A_3'p)_3A$     | >0.3 mM                                      |
| 2'-, 3'-, and 5'-AMP, ADP, ATP    | >1 mM  |
| 2'-, 3'- and 5'-CMP, pCp          | >1 mM  |

The assays were carried out as for Fig. 1. Concentration curves were constructed for each of the compounds tested for which the 50% displacement values given were obtained. Essentially identical results to those shown in Fig. 1a and Table 1b were obtained using the RI assay with <sup>3</sup>H-(A<sub>2</sub>'p)<sub>2</sub>A as probe except that the assay was approximately 20-fold less sensitive, reflecting the lower specific activity of this material.

\* In the RI and RB assays the radioactive probes were  $(A_2'p)_2A$ -[<sup>32</sup>P]pCp and  $ppp(A_2'p)_3A$ -[<sup>32</sup>P]pCp respectively.

**Fig. 1** Radioimmune (RI) and radiobinding (RB) assays for A2'p5'A2'p5'A, pppA2'p5'A2'p5'A and related oligonucleotides. *a*, The RI assay. Inhibition of the binding of (A2'p)<sub>2</sub>A-[<sup>32</sup>P]pCp to (A2'p)<sub>2</sub>A antiserum by different concentrations (abscissa) of unlabelled (A2'p)<sub>2</sub>A, (○); (A2'p)<sub>3</sub>A, (▲); A2'p5'A, (△); (A3'p)<sub>2</sub>A, (●) and adenosine (×). *b*, The RB assay. Inhibition of the binding of ppp(A2'p)<sub>3</sub>A-[<sup>32</sup>P]pCp to the 2-5A-dependent nuclease by different concentrations (abscissa) of unlabelled ppp(A2'p)<sub>2</sub>A, (○); ppp(A2'p)<sub>3</sub>A, (▲); pppA2'p5'A, (△); (A3'p)<sub>2</sub>A, (●) and adenosine, (×). The RI assay (55 μl) contained 3,000 c.p.m. of (A2'p)<sub>2</sub>A-[<sup>32</sup>P]pCp ( $1-3 \times 10^6$  Ci mol<sup>-1</sup>), 15 μl of the sample being tested and 25 μl of a 1:2,000 dilution of antiserum. All dilutions were in Tris-HCl-buffered saline pH 7.6 (TBS); 0.1% gelatin. Incubation was for 1 h at 30 °C. Samples (40 μl) were applied to nitrocellulose filter discs (2.5 cm diameter, 0.45 μm pore size; Sartorius) which were washed in three changes of TBS, dried and counted in a toluene-based scintillant. The RB assays (20 μl) contained 3,000 c.p.m. of ppp(A2'p)<sub>3</sub>A-[<sup>32</sup>P]pCp ( $1-3 \times 10^6$  Ci mol<sup>-1</sup>), 2 μl of competitor, 10 μl of a post-mitochondrial supernatant fraction<sup>19</sup> from Ehrlich ascites tumour cells as the source of the 2-5A-dependent nuclease and 8 μl of 20 mM Tris-HCl pH 7.6, 8.5 mM magnesium acetate, 1 mM ATP and 5% glycerol (v/v). Incubation was for 60 min at 0 °C. Samples (19 μl) were applied to pre-wet nitrocellulose filters as above which were washed in TBS, dried and counted. In both assays the conditions were chosen to give 30 to 50% binding of the radioactive probe in the absence of competitor. This corresponds to the 100% point of the ordinate. The (A2'p)<sub>2</sub>A antiserum was prepared in rabbits with (A2'p)<sub>2</sub>A bound to bovine serum albumin as antigen<sup>20-22</sup>. The 5'-[<sup>32</sup>P]pCp labelled derivatives were synthesized with T<sub>4</sub> RNA ligase and purified by HPLC (R.H.S., unpublished results and ref. 22).

displace 50% of the bound <sup>32</sup>P-labelled derivative in comparison with the concentration of pure core or 2-5A required to produce a similar displacement. (A similar nitrocellulose filter procedure, but for the detection of the nuclease, was used by Slattery *et al.*<sup>10</sup>.)

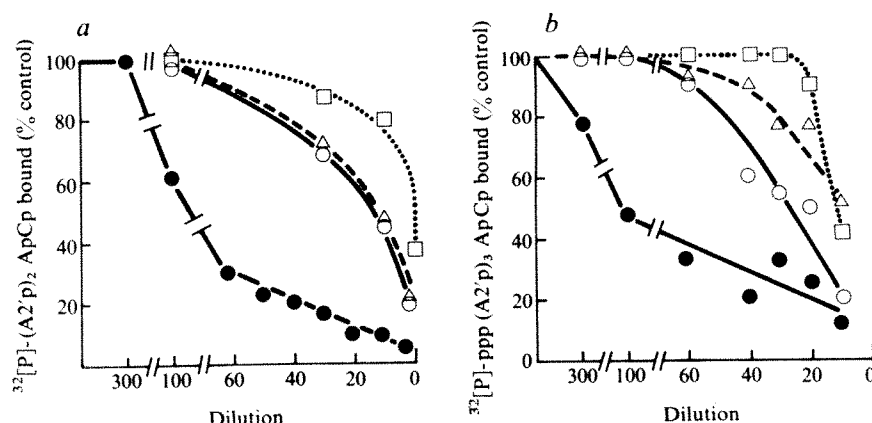

The difficulty in developing suitable assays has been in the production of 2-5A of sufficiently high specific activity (to detect  $\leq 10$  μl of nanomolar 2-5A). In our experience, very poor yields of 2-5A are obtained with the 2-5A synthetase when substrate (ATP) concentrations of  $\leq 100$  μM are used, making the production of 2-5A of specific activity  $\geq 10,000$  Ci per mole of nucleotide costly and impractical. Accordingly, here we have utilized T<sub>4</sub> RNA ligase<sup>14,15</sup> to label preformed (A2'p)<sub>2</sub>A or ppp(A2'p)<sub>n</sub>A ( $n = 2$  or  $3$ ) with [5'-<sup>32</sup>P]pCp to specific activities of  $2-3 \times 10^6$  Ci per mole of oligonucleotide.

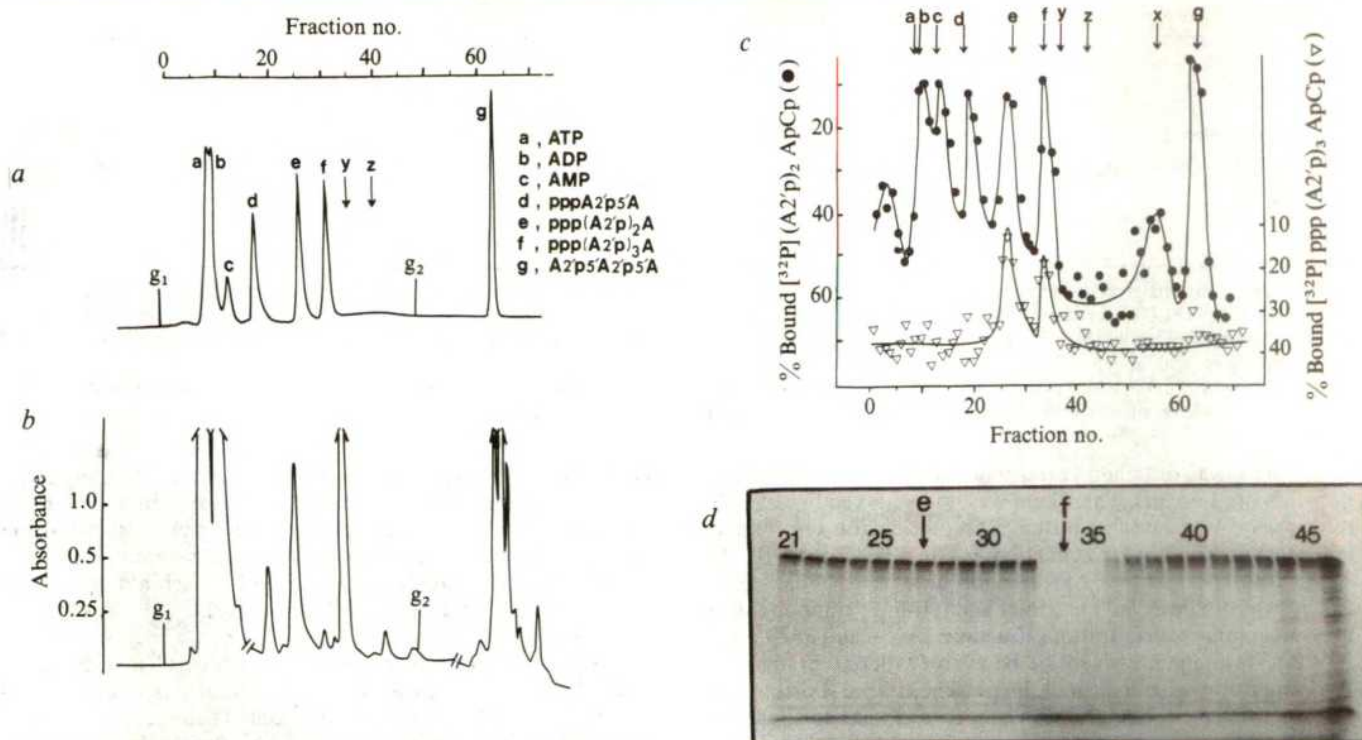

The RI assay shows high but incomplete specificity for the 2'-5' linkage (Fig. 1a, Table 1a). Fifty per cent displacement of the radioactive probe is observed with nM (A2'p)<sub>2</sub>A or (A2'p)<sub>3</sub>A (○, ▲, Fig. 1a) and 10 nM A2'p5'A (△, Fig. 1a). The concen-

tration at which other potentially cross-reacting materials displace 50% of the probe are given in Table 1a. The RI assay provides a sensitive method for the detection of core but without prior fractionation it cannot be used to measure core in the presence of higher concentrations of 2-5A (Table 1a). In addition, problems will arise in the assay of crude material of low titre if it contains sufficient AMP, ADP and ATP to yield  $\geq 500$  μM adenosine on dilution into the assay after digestion with bacterial alkaline phosphatase (BAP), or  $\geq 10$  μM 3'-5' (Ap)<sub>n</sub>A ( $n = 2$  or  $3$ ) (Table 1a). It is possible that other 3'-5'-linked oligonucleotides may also cross-react.

The RB assay shows even greater specificity for 2-5A (Fig. 1b and Table 1b). The 5' triphosphorylated (○, Fig. 1b) and diphosphorylated (Table 1b) trimer, the tetramer (▲, Fig. 1b) and pentamer (Table 1b), all displace 50% of the bound probe at nanomolar concentrations. In fact it shows almost as great a specificity as the 'biological' assays for 2-5A. It falls short of this in detecting relatively low concentrations of the trimer 5'-monophosphate and higher concentrations of core (Table 1b),

**Fig. 2** Radioimmune (a) and radiobinding (b) assays for the natural occurrence of 2-5A in extracts from interferon-treated, EMC virus-infected (●); interferon-treated (○); EMC virus-infected (△) and control (□) mouse L-cells. The assays were carried out as described in Fig. 1 legend. The 100% values correspond to 1,300 c.p.m. representing the 30 to 50% of the radioactive probes bound in the absence of competitor. Mouse L-cells ( $0.75 \times 10^6$  cells) were treated for 17 h at 37 °C with 400 reference (20 effective) units per ml of partially purified ( $5 \times 10^7$  reference units per mg of protein) mouse interferon, infected with 20 plaque-forming units (PFU) per cell of EMC virus and incubated for 4 h at 37 °C. Interferon-treated cells and control cells with or without EMC infection were incubated in parallel. Cells were collected, washed and the packed cells (2.5 ml) lysed into an equal volume of 0.5% NP40 in 10 mM HEPES buffer pH 7.5; 90 mM KCl; 1.5 mM magnesium acetate at 0 °C. Trichloroacetic acid (50%) was added immediately to 5% and the mixture centrifuged at 2,000g for 20 min. The supernatant solutions were extracted 10 times with water-saturated ether, lyophilized and resuspended in 500 μl of 10 mM HEPES buffer pH 7.5 (the pH was adjusted to 7 with NH<sub>4</sub>OH). These extracts were assayed with (radioimmune) or without (radiobinding) prior BAP digestion (40 units of enzyme (Sigma) per ml overnight at 30 °C). Control experiments in which radioactive 2-5A or core (200 nM) were added at the time of cell lysis showed recovery through the remainder of the procedures to be  $\geq 50\%$ .

**Fig. 3** HPLC analysis of 2-5A from interferon-treated EMC virus-infected L-cells. *a*, A mixture of standards containing ATP, ADP, AMP and the dimer trimer, tetramer and core of 2-5A (a-g). The positions y and z at which A5'p45'A2'p5'A2'p5'A and NAD2'p5'A2'p5'A, respectively, eluted in parallel runs are also indicated on the figure. *b-d*, Cell extract (150  $\mu$ l) from 0.75 ml of packed cells. *b*, Absorbance profile: absorbance was measured at 256 nm and at fraction 17 and fraction 57 the full-scale deflection (2.56) was reduced twofold (to 1.28) and 32-fold (to 0.08). *c*, RB assay: column fractions (5  $\mu$ l) were assayed for their ability to displace ppp(A2'p)3A- $^{32}$ P]pCp and RI assay: column fractions (15  $\mu$ l) were assayed after BAP digestion (as in Fig. 2) for their ability to displace (A2'p)2Ap- $^{32}$ P]pCp. The amounts of trimer, tetramer and core detected in the RI assay were unaffected by prior digestion of the fractions with ribonuclease T<sub>2</sub>. This excludes any possibility that the titres obtained reflect the presence of as yet unidentified cross-reacting 3'-5'-linked material. *d*, Nuclease assay<sup>17</sup>: fractions (25-46 and 58-70) (1  $\mu$ l) were analysed for their ability to activate a nuclease and degrade  $^{32}$ P-RNA in a reticulocyte lysate system<sup>17</sup>. Activation of the nuclease by: C, no additions; S1-6, 0.02, 0.06, 0.2, 0.6, 2.0 and 6.0 nM 2-5A tetramer standard; D1-5, dilutions, 1,250-, 375-, 125-, 37.5- and 12.5-fold of the interferon-treated, EMC virus-infected L-cell extract. The interferon treatment and EMC infection of the L-cells and preparation of the trichloroacetic acid extracts were as described in Fig. 2 legend. The HPLC analysis was on a  $\mu$ Bondapak C18 column (Waters Associates) run in 50 mM ammonium phosphate, pH 7.0 at 1 ml min<sup>-1</sup> with a 25-min linear gradient of 50:50 methanol:water applied at g<sub>1</sub> to reach a final of 20% of the total flow by g<sub>2</sub> where the methanol:water was increased to 50% in a 5-min gradient. This second gradient does not separate the 2'-5'-linked oligomers. Good separation of these can be achieved if a shallower gradient is applied at g<sub>2</sub>. The individual 2'-5' and 3'-5'-linked core from the corresponding 3'-5'-linked core components can be resolved in a gradient of methanol in 4 mM potassium phosphate pH 6.5. (It is advisable in the routine analysis of cell extracts that a dry packed pre-column should be inserted to protect the main column.)

both of which are without effect in the activation of the 2-5A-dependent nuclease or on cell-free protein synthesis. All of the other potentially cross-reacting materials tested were essentially without effect (Fig. 1*b*, Table 1*b*).

The specificity is sufficient for the RB assays to be performed with crude cell extracts as the source of the 2-5A-dependent nuclease as binding protein. The results presented here were obtained with post-mitochondrial supernatant fractions from Ehrlich ascites tumour (EAT) cells and very similar results have been obtained with rabbit reticulocyte lysates. It is possible that crude extracts of this type contain other proteins which contribute to the specific binding of 2-5A. However, the results obtained after partial purification of the nuclease and in experiments involving the analysis of radioactive 2-5A covalently bound to protein in such extracts favour the nuclease as the major component involved (D.H.W., C.S.G., R.H.S. and I.M.K., unpublished results). Less extensive studies with similar extracts from HeLa and L-cells suggest that they (and probably any extract containing significant amounts of the 2-5A-depen-

dent nuclease) can also be used in this type of assay. Care should, however, be taken to monitor for significant degradation of 2-5A by such extracts in the development of suitable assays<sup>9,16</sup>.

Despite the relatively high specificity of the RI and RB assays, the exclusion of cross-reacting material is potentially a problem in the assay of crude extracts. Nevertheless, in agreement with our previous results using 'biological' assays<sup>17</sup>, both the RI (after BAP) and RB assays (Fig. 2*a* and *b*, respectively) indicated relatively high concentrations (~100 nM in trimer equivalents) of 2-5A±core in a trichloroacetic acid-soluble extract from interferon-treated, EMC virus-infected mouse L-cells (●) and only much lower concentrations in corresponding extracts from interferon-treated (○), or EMC-infected (Δ), or control (□) cells. That the majority of the material registering in these assays was indeed 2-5A or core was confirmed by HPLC.

The results presented in Fig. 3*b-d* are of an HPLC analysis of an acid-soluble extract from interferon-treated, EMC virus-infected mouse L-cells. The eluates were first assayed by their ability to activate a nuclease in reticulocyte lysates (Fig. 3*d*)<sup>17</sup>. A

**Table 2** Levels of 2-5A and related oligonucleotides in interferon-treated and control mouse L-cells with or without EMC virus infection

| Pretreatment of cells        | Concentration in the intact cell (nM) |          |       |                 |                 |

The concentrations given are based on the packed cell volumes from which the extracts were made. They are calculated from the concentrations recovered after HPLC analysis carried out as for Fig. 3. No allowance has been made for losses during the extraction and processing of the samples. Control experiments in which 2-5A and the related oligonucleotides (50 nM) were added at the time of cell lysis indicated that the recovery of each component was  $\geq 50\%$ .

\* In one experiment in which two- to fourfold higher concentrations of 2-5A were found in the interferon-treated cell extracts (with or without EMC infection) a low level of core ( $\leq 8$  nM) was detected in the extract from EMC-infected cells.

single peak was obtained corresponding to the tetramer (fractions 33–36, Fig. 3d). The trimer was not observed because the reticulocyte nuclease is unusual in requiring the tetramer or higher oligomers for its activation<sup>17</sup>. The RB ( $\nabla$ ) and RI ( $\bullet$ ) assays (the latter after BAP digestion of the individual HPLC fractions) both detected the trimer and tetramer components of 2-5A at similar concentrations (fractions 25–30 and 33–35, Fig. 3c). Interestingly, however, the RI assay (with or without prior BAP digestion) also indicated the presence of pre-existing core ( $\bullet$ , fractions 62–64, Fig. 3c) in amounts similar to those observed for the phosphorylated components. Further HPLC analysis of this material using a gradient of methanol in 4 mM potassium phosphate pH 6.5 showed it to consist largely of the trimer core ((A2'p)<sub>2</sub>A). There was no evidence for significant breakdown of 2-5A to core in control experiments in which low concentrations (<100 nM) of 2-5A were added at the time of cell lysis. This, together with the results of experiments in which the time taken to wash and disrupt the cells was deliberately varied, suggests that the core is not an artefact.

The RI assay also detected dimer ( $\bullet$ , fractions 19–21, Fig. 3c) and cross-reacting material in fractions 1–15 which is probably adenosine produced by the BAP digestion of ATP, ADP and AMP. The concentration of this material is high compared with that in the corresponding control extract (not shown). This emphasizes the necessity for HPLC or alternative additional analysis of material detected by the RI assay in crude extracts in order to establish its identity.

The nature of peak X (Fig. 3c) is not known. It does not seem to be 2-5A joined to NAD<sup>13</sup>. The latter has been synthesized *in vitro* from NAD and ATP with the 2-5A synthetase bound to poly(I)-poly(C)-paper in conditions similar to those used for 2-5A<sup>2,6,13</sup>. The products NAD2'p5'A and NAD2'p5'A2'A were purified by chromatography (on DEAE-cellulose) and the structure of the latter was confirmed by proton NMR spectroscopy. On HPLC analysis the product NAD2'p5'A2'p5'A (Z, Fig. 3a) eluted after NAD. It can be detected at nanomolar concentrations using the RB assay. With the extract from interferon-treated, EMC-infected cells, only very low levels of material (equivalent to  $\leq 5$  nM of putative NAD2'p5'A2'p5'A) were detected in this region of the gradient (Fig. 3c). Control experiments in which NAD2'p5'A2'p5'A at 50 nM was added at the time of cell lysis have shown 75% recoveries. Similar results have been obtained in a less extensive investigation into the possible presence of A5'p<sub>4</sub>A2'p5'A2'p5'A (Y, Fig. 3a, c). It is unlikely, therefore, that either NAD or A5'p<sub>4</sub>A (ref. 18) modified by the addition of 2-5A occurs naturally in these cells at concentrations greater than 5 nM.

Similar HPLC analysis of extracts from interferon-treated L-cells and from EMC virus-infected L-cells, have shown that they contain 2-5A and (in the case of the interferon-treated cells at least) core at lower concentrations (Table 2). It is not yet clear whether very low levels (3 nM in the intact cell) of core and 2-5A are also present in control extracts (Fig. 2 and Table 2).

The results presented establish the validity of the RI and RB assays to detect core and 2-5A. They are now the methods of

choice for the assay of preformed core and 2-5A being much more convenient than the 'biological' assays. In addition the assays are suitable for the routine screening of cells and tissues for 2-5A. The identity of any putative 2-5A components or 2-5A-related oligonucleotides detected in such material must, however, be confirmed by further HPLC (or alternative) analysis.

The natural occurrence of 2-5A and 'core' in interferon-treated cells, although at lower concentrations than in interferon-treated EMC virus-infected cells (Table 2), emphasizes the possible involvement of the 2-5A system in the cell growth inhibitory activity of interferon. The presence of low levels of 2-5A in virus-infected cells may reflect the low levels of synthetase known to be present in the absence of interferon treatment and its activation by viral double-stranded RNA<sup>6</sup>.

The natural occurrence of substantial amounts of core (Table 2) is of considerable interest and emphasizes that in the analysis of the 2-5A system it is not adequate to measure only 2-5A. The amount of core seems to be independent of the concentration of 2-5A and it may, therefore, play a separate role in the inhibition of DNA synthesis and cell growth.

We thank B. F. Erlanger and S. Zakarian for advice in setting up the radioimmune assays, B. F. Erlanger for antisera to 3'-5'-linked ApApA used in preliminary studies, and S. Jones and C. B. Reese for chemically synthesized 2-5A trimer, 5'-mono-, di- and triphosphates. M.K. was the recipient of a grant from the government of Ghana and D.H.W. of an EMBO fellowship.

# MATTERS ARISING

## Origin of mammal-like reptiles

KEMP<sup>1</sup> has recently hypothesized that "the synapsid [mammal-like reptile] skull evolved from a limnoscelid-like skull rather than from that of a romeriid, and that the temporal fenestra of the mammal-like reptiles evolved directly from the remnant of the crossopterygian hinge line". This disagrees with the widely accepted theory that the Protorothyrididae (Romeriidae), a group of small reptiles with unfenestrated skull roofs, include the ancestors or near-ancestors of the Pelycosauria, the earliest synapsid or mammal-like reptiles<sup>2-4</sup>. Both Kemp<sup>1</sup> and Reisz<sup>5,6</sup> have recognized that the protorothyridid skull is advanced in some cranial features compared with pelycosaurids and, hence, could not be ancestral to the primitive pattern of early synapsids. Kemp's hypothesis replacing a protorothyridid ancestor with a "limnoscelid-like" ancestor also seems invalid.

Kemp uses the common occurrence of a large supratemporal that contacts the postorbital, and a large tabular that contacts the paraoccipital process of the opisthotic, as the basis of his hypothesis. These, however, are primitive tetrapod characters present in virtually all primitive amphibians and reptiles. Thus they have no phylogenetic significance in the context of synapsid origins. The proper methodology for developing a theory of phylogenetic relationships of any group of organisms is to study the distribution pattern of morphological characters among a whole range of generally similar organisms so that a determination of whether a particular character is primitive or derived may be made (only derived characters are of any significance when trying to deduce phylogenetic relationships). Because Kemp has failed to do this, he has been badly misled by phylogenetically insignificant primitive characters.

The thesis that the synapsid temporal fenestrae evolved directly from a remnant of the crossopterygian hinge-line between the skull roof and cheek is untenable. There is no evidence that any true cotylosaur, including seymouriamorphs or diadectomorphs (limnoscelids belong to the latter group<sup>7</sup>) or primitive reptiles, ever had a cardinal line of weakness (or hinge) between the skull roof and cheek in the living animals. The presence of such a feature in the above animals is an old misconception based on the fact that post-depositional crushing tends to concentrate forces along the sharp angle between the skull roof and cheek leading to breakage of the bone or suture. The only known skull of *Limnoscelis* is compressed dorsolaterally so that the bone has broken in this region to give the impression of a

hinge, or line of weakness. As Heaton<sup>8</sup> has noted, this often happened in captorhinomorphs as well, where there was a solid wide suture between the skull roof and cheek. The only known specimen of *Romeriscus*, a possible limnoscelid on which Kemp placed much emphasis, is so poorly and incompletely preserved that it cannot be used as the basis of a major hypothesis.<sup>9</sup>

Hypotheses on the origin of the Synapsida based on the development of the temporal fenestrae<sup>10</sup> are inappropriate because these are not restricted to them (lateral temporal fenestrae are present in mesosaurs, bolosaurs, diapsids and some millerosaurs) and because fenestration is only one aspect of the development of the synapsid skull. Any hypothesis of the origin of the synapsid reptiles should be linked to the structural innovations seen in the braincase, occiput, adductor chamber, mandibles and dentition as a whole, because these changes gave rise to a morphological complex that is unique among higher vertebrates.

KEMP REPLIES—Reisz and Heaton's criticism of the use of primitive characters to demonstrate phylogenetic relationships ignores my specific disclaimer that I was proposing any particular relationship between limnoscelids and synapsids. My object was simply to suggest that the character-state of the temporal region of the skull of the direct ancestor of synapsids resembled that retained in the limnoscelids, for example, and not that of romeriid or protorothyridid reptiles. Of course any hypothesis about the phylogenetic relationships of synapsids to particular tetrapod groups would require a comprehensive study of the distribution of derived characters of the whole skeleton. It was for this reason that I

carefully avoided any taxonomic implications at all, and indeed the possibility of a primary sister-group relationship between romeriids and synapsids is nowhere excluded.

The exact nature of the connection between the skull table and cheek of *Limnoscelis* is difficult to determine from a single, damaged skull. Even if the 'hinge-line' is merely the consequence of distortion, as Reisz and Heaton now claim, the similar manner of breakage of the two sides of the skull, between the table and the cheek, suggests nevertheless that this line was weak. So also does the fact that the suture between the post-orbital and squamosal is continued posteriorly in a straight line by the suture between the supratemporal and squamosal to the hind margin of the skull. My contention that the synapsid temporal fenestra appeared within this suture line remains unaffected, even if the contact between the respective bones was rather firmer than supposed. There would still have been a thin layer of connective tissue between the bones, as in the case of any suture, which could have expanded, eventually forming the temporal aponeurosis.

## Growth rings in dinosaur teeth

THERE are several difficulties with Johnston's interpretation of the growth rings he has observed in dinosaur teeth<sup>1</sup>. The first problem is whether the rings are annual. Such growth rings are found in living and fossil ectothermic vertebrates, but in the bones, not the teeth, which are replaced frequently in most non-mammalian vertebrates<sup>2</sup>. The teeth of crocodiles are replaced at intervals of 8-16 months<sup>3</sup>, making it impossible for more than two annual rings to occur within any given tooth. There is no evidence that replacement ceases during adult life, nor that the rate was substantially different in fossil crocodilians. Data on the manner and rate of tooth replacement for dinosaurs are limited, although evidence suggests multiple replacement and rapid turnover<sup>2</sup>.

Dinosaurs and crocodiles would be expected to share some similarities in hard-tissue deposition and to differ from mammals, for the ancestors of archosaurs and mammals were separated perhaps as

far back as latest Carboniferous<sup>4</sup>. Johnston ignores conclusions based on extensive studies of fossil reptile bones<sup>5</sup> which show that dinosaur bone resembles more that of large living endotherms than ectotherms. He argues that, because crocodiles are ectothermic and their teeth are similar to those of dinosaurs, then dinosaurs also must have been ectothermic. But similar teeth are also found in Cretaceous birds<sup>6,7</sup>, implying either that they were ectothermic or that dental growth rings are not a sufficient indicator of overall physiology.

The precise connection between growth rings and thermal physiology is unknown, and it is likely that a complex set of phenomena is involved. Mammalian growth rings appear in constant as well as seasonal environments<sup>8</sup>; neither temperature nor moisture are proven causal factors. Endo/ectothermy is not a sharp dichotomy, but a continuous spectrum, as is homeo/poikilothermy<sup>9</sup>. Calcium stress may be due to seasonal, dietary, reproductive, structural, phylogenetic or other poorly understood influences; the pitfall of 'one-factor' ecology is that no one factor, internal or external, is likely to explain all observed metabolic responses. Mammals and birds have used various strategies to solve problems in energetics; the diversity of dinosaurs suggests that many physiological solutions may also have been available to them<sup>10</sup>. It seems imprudent to rule out other factors contributing to the growth of hard tissues merely because they cannot be accounted for.

CONTRARY to Johnston's interpretation, the skeletal annuli he observed in dinosaur teeth<sup>1</sup> need not imply any seasonal temperature fluctuation but may simply be a result of seasonal variation in food resources created by seasonal rainfall patterns. Spinage<sup>2</sup> has shown that two distinct annual cementum lines are

formed in the teeth of African buffalo (*Syncerus caffer*) from regions with bimodal precipitation whereas one exceptionally distinct annulation forms each year in buffalo from southern Tanzania where rainfall patterns are unimodally seasonal. Also, desert bighorn sheep (*Ovis canadensis*) possess annuli in both cementum and dentine resulting from a cessation of growth during dry summer months<sup>3</sup>. These observations of seasonal dental annuli formation in endotherms counter Johnston's arguments for ectothermy in dinosaurs.

MARK S. BOYCE

JOHNSTON<sup>1</sup> claims that 'growth zones' observable in dinosaur teeth give tooth age in years, and suggest that dinosaurs were crocodile-like ectotherms. Individual ages in many mammalian species can be determined by counting various types of growth rings, including those in dentine. But if the results are not checked against individuals of known age<sup>2-4</sup>, serious errors can be made. One possibility is that annual growth lines are confused with the contour lines of Owen. Johnston says that there are "two main types of rings" in dinosaur teeth, with the implication that annual rings are easily distinguished. Studies on mammalian teeth suggest that true annual rings are apparently formed in the same way as, and are morphologically similar to, contour lines of Owen<sup>2</sup>.

In the absence of studies on a living relative or other acceptable analogue, it is easy in growth ring studies for hypothesis to bias observations. We suspect that Peabody's paper<sup>5</sup> cited by Johnston gives an example of this. Peabody recognized as many as four annual growth zones in some teeth of the small Lower Permian reptile *Captorhinus*. Although he did not discuss tooth replacement, a common opinion among vertebrate palaeontologists at the time was that the teeth of *Captorhinus* were not replaced. It would have been reasonable to expect individual teeth to persist for 4 yr. However, it is now known that all the teeth of *Captorhinus* were being actively replaced<sup>7</sup>. It is unlikely that a single tooth in such a small animal would persist for 4 or more years; Peabody's 'annual growth zones' probably reflect a less than annual periodicity if they had a regular periodicity at all.

Because dinosaurs are extinct Johnston's 'annual growth zones' cannot be verified, and his counts can at best be established only as more or less reason-

able by study of living animals. The crocodilians are the closest living toothed relatives of dinosaurs, but there is no substantial evidence as to how long their teeth last or whether they can be aged by counting growth zones. Although Edmund<sup>8</sup> found a life span of slightly more than 2 yr in *Alligator* teeth, his specimens were very small and do not provide a good parallel with dinosaurs. Neill<sup>9</sup> states that old alligators cease replacement and may become nearly toothless. Even if this is confirmed, it tells us nothing about the age of the remaining teeth or the number of growth zones they may contain. In any case Johnston's counts of eight annual rings in each of two tyrannosaur teeth seems rather high (though not impossible) in view of the fact that tyrannosaurs, as well as the other dinosaurs he cites, show active tooth replacement<sup>6,10</sup> which seems to have continued throughout life as we know of no evidence to the contrary.

Johnston notes that de Ricqlès' histological surveys<sup>11,12</sup> did not reveal seasonal growth rings in dinosaur bone. However, histology did not simply produce negative evidence. de Ricqlès argued cogently, on the basis of long-bone histology, that dinosaurs were probably relatively endothermic. Absence of cyclical growth lines in dinosaur periosteal bone was attributed to the rapid growth characteristic of endotherms. The growth zones observed in dinosaur teeth thus should not be considered in isolation; their interpretation must be consistent with a total histological picture that includes the rest of the skeleton.

Johnston's suggestion of crocodile-like endothermy in dinosaurs at first appears to contradict de Ricqlès, but the latter noted that animals may be neither fully endothermic nor fully ectothermic and that, although dinosaurs were relatively endothermic, they probably had their own peculiarities in thermal physiology. It is impossible to correlate environmental and/or endogenous factors with the formation of growth zones in dinosaur teeth. But even if Johnston is right in calling these growth rings seasonal, their existence simply suggests that de Ricqlès was right in supposing that dinosaurs were not completely comparable to large mammals in thermal physiology. It does not imply, in view of the total histological evidence that dinosaurs were crocodile-like ectotherms.

JOHNSTON REPLIES—Meinke *et al.* acknowledge that annual layers occur in bone of fossil (and living) ectotherms but deny that the similar rings which occur in the dentine of those animals are annual or even extrinsically induced by the change in seasons. Irrespective of anything else, however, this view is illogical: dentine is itself simply acellular bone. Furthermore, in Recent temperate and arctic terrestrial mammals<sup>1,2</sup> (marine mammals, cited by Meinke *et al.*, are ecologically inappropriate as analogues of terrestrial crocodiles and dinosaurs): (1) the most conspicuous dentine bands form simultaneously with annual layers in periosteal bone, and (2) dentine has been shown to be a sensitive indicator of annual, seasonally induced disruptions of growth. Meinke *et al.* give no evidence that the dentine in ectotherms (living or extinct) behaves differently.

Boyce, noting that severe seasonal contrasts can produce rings in the dentine of certain terrestrial mammals, overlooks my citation of the same phenomenon<sup>3</sup>; and Boyce provides no evidence that Alberta dinosaurs lived in seasonally xeric conditions comparable to those of desert bighorn sheep. Instead, palaeontological evidence<sup>4,5</sup> indicates that the western interior of North America was a humid, warm temperate to subtropical environment without extreme seasonal fluctuation of precipitation and temperature during Late Cretaceous time.

Bolt and DeMar cite possible uncertainty in distinguishing the boundaries of annual layers in dentine (and bone) owing to the production of accessory bands (accentuated contour lines of Owen); however, these difficulties no more detract from the reality of seasonal disruptions in dentine deposition than does the occurrence of false annuli negate the phenomenon of true annuli in fish scales. Furthermore, annual layers in the calcified tissues of Recent terrestrial mammals (and by extrapolation, crocodiles and dinosaurs) can usually be distinguished: they are more pronounced and regularly spaced than are accessory bands<sup>1,2</sup>.

Meinke *et al.* err in claiming the impossibility of finding more than two annual rings within a crocodile tooth: the number of annual layers in crocodile dentine gives the age of the tooth (minimum age if the pulp cavity is occluded), not just its functional age. In one 100-yr-old crocodile<sup>6</sup>, each tooth probably has been replaced about 50 times—an average of about once every 2 yr. In the Nile crocodile, two or three replacing teeth can be lodged beneath a functional one, and as many as six replacing teeth have been recorded at a single locus<sup>6</sup>. Thus, in a mature individual, a tooth could easily reside in the jaw for 4 yr, two before eruption and two after (longer if more than one successional tooth occurs below a given functional tooth), resulting in the accumulation of four annual layers in the dentine.

The number of major bands in dinosaur teeth is consistent with probable replacement rates: a maxilla of *Antrodemus* sp. (Princeton University Museum No. 16554-9), for example, exhibits three generations of teeth<sup>7</sup>, and if the average tooth replacement interval in mature *Antrodemus* was 2 yr (not unreasonable by analogy with Recent crocodiles), each tooth must have been held for 6 yr (4 yr before eruption and two while functional), yielding six annual layers in the dentine. If the replacement interval ranged from 1 to 3 yr during the life of an individual, the total life of a given tooth could be from 3 to 9 yr depending on the age of the individual. Although absolute replacement rates are not known for dinosaurs, relative rates can sometimes be inferred: hadrosaur and ceratopsian teeth, which are stacked for evident rapid replacement in a specialized grinding mill, generally have fewer rings than do carnosaur teeth, the function of which is not dependent on occlusal wearing of crowns.

Bolt and DeMar's model<sup>8</sup> of tooth replacement in *Captorhinus* describes the pattern of replacement but says nothing of rate. Small size alone is not necessarily indicative of rapid replacement: *Sphenodon* (Rhynchocephalia) and certain acrodont lizards are *Captorhinus*-sized or smaller, yet the lateral teeth wear heavily with age and are probably not replaced at all in mature individuals<sup>9</sup>. There is no histological evidence to support Bolt and DeMar's model of rapid replacement (in fact, heavy wear on many specimens of *Captorhinus*<sup>8,10</sup> suggests relatively slow replacement) nor can the model account for the occurrence of the tallest teeth at or near the centre of the rows of teeth, a definitive feature of *Captorhinus* multiple-rowed dentitions<sup>11</sup> (R. C. Fox, personal communication). Consequently, Peabody's interpretation<sup>12</sup> of growth zones in *Captorhinus* teeth remains a reasonable one.

Mesozoic toothed birds do not show dinosaur or crocodile-like zones in their

teeth (*contra* Meinke *et al.*) (see Yale Peabody Museum specimens 1206, 1474, uncatalogued thin-sections, all teeth of *Hesperornis*, YPM 1728, teeth of *Ichthyornis*); possibly Meinke *et al.* observed ringed teeth in small mosasaur (*Lepidosauria*) jaws (having lacertilian rows of nutritive foramina), for dentigerous fragments of two such jaws are in the Yale toothed-bird collections (R. C. Fox, personal communication).

Meinke *et al.* attribute the undeniably close resemblance of dentinal rings in dinosaurs and crocodiles to phylogenetic propinquity. *Champsosaurus*, a Late Cretaceous-Eocene eosuchian (and undoubted ectotherm), displays dentinal rings like those in Upper Cretaceous dinosaurs and crocodiles. Would Meinke *et al.* explain this in terms of "phylogenetic propinquity" of archosaurs and eosuchians, groups whose last common ancestry is no younger than Permian and perhaps Carboniferous<sup>13</sup> (almost as remote as for archosaurs and mammals)?

Phylogenetic 'explanations' only describe results of process, not process itself (at least for those who believe natural selection is the source of adaptive resemblance between organisms), and it is clearly self-contradictory that resemblances purported to stem from phylogenetic relationship would have completely different physiologic origins, as Meinke *et al.* would have us believe.

Finally, Meinke *et al.* argue that, owing to their diversity, dinosaurs might be expected to show a range of physiological thermoregulation. Perhaps, but if so diversity by itself will not carry the argument: after all, Recent reptiles are far more diverse taxonomically than are dinosaurs, yet all are ectothermic.

I thank J. Osborn, D. Wigglesworth, R. C. Fox and R. Barwick for helpful comments.

## Feroxyhyte on Mars?

BURNS discussion<sup>1</sup> on the possibility of the mineral feroxyhyte occurring on the surface of Mars is potentially misleading. In the original description of this mineral Chukhrov *et al.*<sup>2</sup>, following Feitknecht<sup>3</sup>, distinguished between a strongly magnetic phase,  $\delta$ -FeOOH, and a "practically nonmagnetic" phase  $\delta'$ -FeOOH. It was the weakly or nonmagnetic  $\delta'$  phase to which the mineral name feroxyhyte was applied. Burns seems to have equated the two phases and uses data in support of his hypothesis most of which are derived from the synthetic  $\delta$ -FeOOH. The difference may be of more than semantic significance because the ferromagnetic, deep brownish  $\delta$ -FeOOH is formed by the vigorous, rapid oxidation and topotactic replacement of Fe(OH)<sub>2</sub>. As this is a process unlikely to occur in natural conditions at the Earth's surface,  $\delta$ -FeOOH has yet to be reported as a mineral. On the other hand,  $\delta'$ -FeOOH (feroxyhyte), while also requiring the topotactic replacement of precipitated Fe(OH)<sub>2</sub>, is obtained by a slower oxidation and is a yellow-brown ochreous material when dried<sup>2</sup>. This is the mineral reported from marine sediments and gley soils<sup>2</sup>. The yellow-brown colour is almost identical to the description of the soils at the Viking Lander sites<sup>4</sup>. However, if feroxyhyte is nonmagnetic then its major presence on the weak magnets attached to the Viking Lander backhoes<sup>5</sup> is improbable. Chukhrov *et al.* noted that some of the  $\delta'$ -FeOOH samples they studied contained admixed maghaemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) which they felt contributed to the weak magnetism of these individual samples. Thus, on the basis of colour, feroxyhyte ( $\delta'$ -FeOOH) might indeed be a constituent of the surface of Mars and the magnetic experiments may have picked up admixed maghaemite<sup>5</sup>, but the possibility of  $\delta$ -FeOOH on Mars seems remote.

BURNS REPLIES—When it was suggested that feroxyhyte might occur on the surface of Mars<sup>1</sup>, I was well aware<sup>2,3</sup> of the claimed distinction between the ferromagnetic phase  $\delta$ -FeOOH and the terrestrial mineral feroxyhyte ( $\delta'$ -FeOOH). Towe points out that in their original descriptions of feroxyhyte, Chukhrov *et al.* thought the weak magnetism in some  $\delta'$ -FeOOH samples was due to maghaemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) impurities<sup>4,5</sup>. Note, however, that synthetic  $\delta$ -FeOOH phases display variable saturation

magnetization<sup>6-13,17</sup> as a result of particle size variations, implying the coexistence of  $\delta$ -FeOOH and  $\delta'$ -FeOOH in most synthesis products. Maghaemite, too, shows similar tendencies towards superparamagnetism<sup>14-16</sup>. Towe has focused his attention on the magnetic properties of  $\delta$ -FeOOH- $\delta'$ -FeOOH assemblages without commenting on other favourable properties of them relevant to martian geochemistry. I contend that feroxyhyte  $\delta'$ -FeOOH- $\delta$ -FeOOH admixtures must be reckoned as a prime candidate for the colour, chemisorption, spectral, redox, paragenesis and magnetic properties of the surface of Mars.

## Anisotropy of Young's modulus of bone

The Hashin-Rosen model was recently applied by Katz<sup>1</sup> to bone to explain the variation of Young's modulus,  $E$ , for bovine femoral specimen with respect to the orientation of specimen axes cut at the angle  $\phi$  to the long axis of the bone. From Fig. 4 of Katz's report it can be seen that (1) in the case of dry bones  $E$  fell from 20 GN m<sup>-2</sup> at 0° to 13 at 10°. At 20°, 50°, 60° and 70°  $E$  was 13. Only at 30° and 40° was it 14; (2) in the case of wet bone  $E$  was 17 GN m<sup>-2</sup> at 0° then fell steadily to 10 at 50°.  $E$  then increased to 14 at 60°, remained steady at 14 up to 70° and thereafter gradually declined to about 11 GN m<sup>-2</sup>.

If values of  $E$  for the dry and wet bone specimens are considered to be significantly different, water must have an important role in determining the mechanical properties of bone. The Hashin-Rosen model does not take this role into account.

If, on the other hand, values of  $E$  for the dry and wet bone specimens are not considered to be significantly different,  $E$  values between 10° to 80° lie between 13 and 14 GN m<sup>-2</sup>, that is,  $E$  does not seem to be affected by  $\phi$ . This result is contrary to the Hashin-Rosen model. Accordingly, I wonder whether the Hashin-Rosen model can be profitably applied to bone.

1. Katz, *Nature* **283**, 106 (1980).

KATZ REPLIES—Further explanation seems necessary for the role of the Hashin-Rosen calculation in modelling the elastic properties of bone. This is the structural composite phase of the hierarchical modelling. It cannot *per se* account for the effects of wet compared with dry bone. This entails considering the material composite nature of the system during the hierarchical modelling.

First, as I stated<sup>1</sup>, dry bone is stiffer and more rigid than the same specimen when wet. This is attributed to changes in the elastic properties of the organic matrix of bone. Second, the Young's modulus,  $E$ , of bone does vary with angle  $\phi$  as shown by many experimenters for haversian bone, for so-called plexiform bone and for mixed specimens. The bovine bone specimens used by Bonfield and Grynepas<sup>2</sup> probably included all three kinds; unfortunately, they reported no structural observations. Indeed, this might explain why some wet specimens were stiffer than some dry ones (plexiform bone is stiffer than haversian bone).

These facts can be incorporated in the Hashin-Rosen calculation; values of  $E_{GS}$ ,  $\nu_{GS}$ ,  $E_{Ost}$  and  $\nu_{Ost}$  can be adjusted. Thus,  $E(\phi)$  in Fig. 3 of my report is approximately 30% greater than the equivalent  $E(\phi)$  on Fig. 4. Also,  $E(\phi)$  at any angle  $\phi$  can vary as much as 80% (see Fig. 4 of ref. 1) simply by altering the percentage of longitudinal osteonic collagen fibres. Thus, curve *a* of Fig. 4 simulates dry bone, and curves *b*, *c* and *d* in effect simulate wet bone behaviour. In reality, this calculation accounts for the effects of sample variation described above, that is, more longitudinal fibres, and thus stiffer lamellae, so simulating plexiform bone.

Unfortunately, my original report<sup>1</sup> could not be expanded to discuss all this; a longer, more complete paper is being prepared. Finally, a hierarchical model wherein a structural composite is superimposed on a material composite does simulate the elastic properties of bone.

# Environmental issues: how much science, how much politics?

Stephen Cotgrove

THE 1970s could well be remembered as the decade of the environment, a decade that was ushered in by warnings of impending disaster. But it was also a time of controversy. Opinions differed widely both on the nature of the threat to the environment and on its causes and cures. During the decade, the focus of attention shifted from pollution to a growing concern over the exhaustion of fossil fuels and resources. The period also saw the emergence of a more radical environmentalist movement, impatient with mere cosmetic meliorist strategies, arguing that the roots of the environmental crisis lie deep in the structure and values of contemporary society, and that no mere technical fix can solve the problem. Now, in the 1980s, nuclear power looks set fair to become the focus for continuing radical protest.

The controversies spawned a vast literature. Any attempt to master the thousands of articles and books and to achieve some kind of diagnosis and stock-taking is a daunting prospect. These two books, however, are both impressive efforts to generate an interpretative framework. Together with Tim O'Riordan's earlier study (*Environmentalism*; Pion, 1976), they constitute a guide through the massive literature and complexities of the issues.

One conclusion is inescapable. Environmental controversies go far beyond scientific and technical debate about reserves of non-renewable resources, methods for safe disposal of radioactive waste and the "risks" of various methods of generating energy. Pollution, for example, is not a scientific term: it conflates a value judgement. In the words of Mary Douglas, pollution is dirt in the wrong place. Similarly, "safe" systems always entail a judgement about an acceptable level of hazard. Behind controversies about low-level radiation, the routing of a motorway or optimum levels for the control of pollution, there is a hidden agenda involving the increasing powerlessness of individuals to influence decisions affecting their lives and the question of the extent to which economic growth should be at the expense of other values.

There are, of course, other blatant and obvious interests underlying the protest of those who do not want a motorway through their own back gardens or a hydro-electric scheme that might spoil their

*Environment, Ideology and Policy.* By Francis Sandbach. Pp.254. (Basil Blackwell/Allanheld, Osmun: 1980.) Hardback £12.50, \$26.50; paperback £4.95. *The Environment from Surplus to Scarcity.* By Allan Schnaiberg. Pp.464. (Oxford University Press: 1980.) Hardback \$14.95; paperback \$9.95, £6.75.

fishing. But beyond this, environmental policies are essentially political in the sense that the interests of some are safeguarded, while those of others are threatened. The central thesis of Sandbach's book is that it is political ideologies that mould both policy and action.

This point is not easily taken by many who see the debate over nuclear risk, for example, as essentially factual. For them it is a question of an objective analysis of degrees of risk for various sources of energy as the basis for a rational decision to choose those methods which the calculus shows to be least risky. From this perspective the rejection of nuclear power is at best ill-informed, and at worst emotional and irrational. But there is a hidden agenda on both sides of the debate. Both are essentially rooted in the alternative ideologies which Stephen Del Sesto has discussed (*Public Policy* 28 (1); 1980); both come to conclusions which are perfectly sensible and reasonable within their respective frameworks of meaning. The problem is to unpack the debate in such a way that the hidden beliefs and values of both sides are made explicit. Even this will not go far enough. Each side is convinced of the self-evident logic of its own position. In short, the debate is embedded in competing doctrines about the nature of society, and above all, about what are the overriding values that policy should seek to maximize.

Despite the central role which the notion of ideology plays in Sandbach's analysis, nowhere does he unpack the concept. It is necessary to distinguish at least two senses in which the term is used. First, there is the argument that ideology refers to knowledge which is distorted by the interests of different groups. In order to substantiate this usage, it would be necessary to demonstrate ways in which scientific knowledge — of the effects of low-level radiation, for example — is

actually related to interests. Of course, it is easy to show that a substantial proportion of the total scientific effort is related to production and defence. The other side of the coin is to demonstrate that much research does not get done because it is not in the interests of dominant interest groups. Schnaiberg's analysis has essentially the same message: that it is the distribution of economic and political power which shapes the kind of research which does get done. So, argues Schnaiberg, there has been a major emphasis on production research to the relative neglect of research on environmental impacts. But he is more convincing than Sandbach in presenting supporting evidence. Equally important, he provides evidence of the subtle (and not so subtle) pressure in the USA against the communication of evidence contrary to powerful interests. Consequently, he argues, society simply lacks the necessary scientific intelligence for realistic environmental policies.

There is a second sense in which it is possible to distinguish between science and ideology. Whenever knowledge and beliefs are used to justify and legitimize policies and courses of action, science is being put to ideological uses to support particular interests. This does not necessarily mean that the knowledge is distorted by interests. It simply draws attention to the distinction between knowledge and its uses. So when scientists give evidence at public inquiries, they are, willingly or not, caught up in political debate. This may help to explain the lack of confidence and trust in science among environmentalists. The achievements of science in modern industrial societies underlie the generally high respect for science and scientists. To appeal to expert opinion is a powerful weapon in political debate. But to sustain respect, science must be seen to be impartial and objective; it is this that many environmentalists doubt. Interestingly, the appearance of scientists at inquiries has contributed to the erosion of confidence. It has increased awareness of the extent of disagreement: on almost all major issues, expert opinion can be ranged on both sides of debate.

The two books are especially critical of the claims of such techniques as cost-benefit analysis, technology assessment and environmental impact analysis to be objective and scientific. The great

weakness, say both Sandbach and Schnaiberg, is that such approaches fail to investigate the original basis for technological choice. Much of the debate over nuclear power, for example, has focused on its social and environmental consequences without asking what, for Sandbach, is the fundamental question: what are the interests which promote this form of energy? Only by uncovering the hidden agenda can there be a debate about nuclear power which comes to grips with the fundamental issues.

Both books challenge the notion of technological determinism — technology as some independent and impartial force, there being no escape from its imperatives — and explore the ways in which technology is shaped by the economic and political system. Sandbach gives a particularly interesting and thought-provoking account of technology and the environment in China. Chinese economic policy would not be judged efficient in market economy terms precisely because it has sought to incorporate non-economic political goals, such as rural self-sufficiency, worker management of factories, and protection of the natural environment and resources. And it has deliberately sought to develop technologies which are appropriate to the achievement of such goals. This has not, incidentally, been without its environmental problems, notably that of organic pollution in the rural areas.

Sandbach and Schnaiberg, then, make a powerful case for the view that environmental policy goes far beyond technical issues. The way a society treats its environment is rooted in the fundamental structure and values of that society. Science and technology, too, are functions of social systems.

While both books attempt to explore the implications of different political positions for the environment, both are more optimistic about the ability of the left to find benign solutions avoiding the more extreme forms of centralized state control which scarcity may generate. While Schnaiberg manages to avoid obvious partiality, Sandbach is not so successful. He is less than convincing, for example, about the possibility of an "objective" Marxist science, free from political and ideological distortions.

Both books are scholarly and well researched. Both carry the same essential message — that science and technology function within a political context. Few scientists and even fewer technologists will like this. By education and inclination, many would prefer a de-politicized world in which policy is determined by "facts" and expertise. Environmental controversies, however, supply convincing evidence to the contrary. □

Stephen Cotgrove is Professor of Sociology and Director of the Science Studies Centre at the University of Bath.

## At the core of chemical catalysis

F. R. Hartley

*Homogeneous Catalysis: The Applications and Chemistry of Catalysis by Soluble Transition Metal Complexes.* By George W. Parshall. Pp.240. (Wiley-Interscience: 1980.) £14.90, \$35.

THIS book by Dr G. W. Parshall, Director of Chemical Science at du Pont, aims to provide a balanced description of homogeneous catalytic reactions. In this it succeeds admirably. There are few people better qualified to write such a book and everyone involved in the field, student or research worker in an academic or industrial laboratory, will be grateful to Dr Parshall for wading through the enormous literature of homogeneous catalysis to expose the real core of the subject to close scrutiny.

After two brief, but valuable, introductory chapters there follow nine chapters on homogeneously catalysed chemical reactions. All the major industrial processes that use homogeneous catalysis are covered, as well as the more useful laboratory syntheses. Clearly, some selection has been necessary here, but in my judgement it has been well done. The final chapter looks to the future, considering the known as well as likely developments in feedstocks as well as possible future developments in catalysis, including supported metal complex catalysts.

The strengths of this book are many. Foremost amongst them is the air of industrial reality that pervades the whole book. This is beautifully illustrated by the comment that the intensive study of homogeneous olefin hydrogenation catalysts seems anomalous because soluble catalysts are rarely used either in industrial or laboratory hydrogenations. Many of the chapters end with a number of important general references to guide the reader into the wider literature. Key references in the text have been chosen with great care.

This book is one that everyone working in the field of homogeneous catalysis will want to have close to hand, and lecturers will want several copies available in the library for their students. The book summarizes what is known and where the applications of the subject lie; it emphasizes areas in which more research is needed to increase our understanding of the mechanisms of homogeneously catalysed reactions; it provides pointers to the future. I recommend it unreservedly to anyone starting or established in the fields of synthetic, industrial and catalytic chemistry. □

F. R. Hartley is a Professor in the Department of Chemistry and Metallurgy at the Royal Military College of Science, Shrivenham, Wiltshire.

## New ideas about parasites

Donald R. Strong

*Evolutionary Biology of Parasites.* By Peter W. Price. Pp.237. (Princeton University Press: 1980.) Hardback \$22, £9.70; paperback \$8.75, £3.80.

PRICE's thoughtful and ambitious little book is an ecumenical overview which considers phytophages, parasitoids and hemiparasitic green plants, as well as the subjects of classical parasitology, as functional analogues. Such general perspectives have not been of great interest to parasitologists, who are more concerned with details of the taxonomy, life-cycles and pathology of the myriad pests of animals and plants. Price, in contrast, is an ecologist and evolutionist, and as such works in an alternative tradition of broad generalization and synthesis. I hope that this does not deter mainstream parasitologists. Ecologists will read the book; the author's reputation and that of the *Princeton Monographs in Population Biology* ensure this. But biologists who

work on specific parasitic groups have much to contribute to an eco-evolutionary synthesis in parasitology; and much to gain from the book. Ultimate success for Price's efforts towards a synthesis will come only from a rapprochement of these two camps.

After an introduction, chapters on general concepts, non-equilibrium ecology and evolution, genetics, radiation and host-specificity, niches and orthodox community theory, and parasite influences on host evolution follow. Finally there is a coda of ideas for further study.

The most interesting chapter to me is that on communities. Here, Price represents the new academic ecology well, in questioning the basic assumptions of the old, ideal Hutchinsonian school. The most important assumption of the idealists is, of course, that communities are primarily a product of the competitive interactions among their component species. Price meets this head-on with Table 6.1, which shows that the literature indicates non-

Put in the Library  
BIOLOGY COLLECTION  
at the Royal College of Science  
SHRIVENHAM

interactive coexistence to be quite common among species of gut parasite. In summary he says: "There is little evidence to suggest that competition has been an organizing force [for many parasites]". K. Rohde's important overview of species interaction among fish gill parasites was published after this book went to press (*Am. Nat.* 114, 648; 1979), but his earlier work is reviewed. For gill parasites, Rohde comes to a conclusion similar to Price's; so do John Lawton and myself for the phytophagous insects, in a paper now in press (*Am. Nat.*).

Clearly, exceptions to this generalization exist in both zoophagous and phytophagous groups; interspecies competition does sometimes affect coexistence. But the great preponderance of cases involve loose organization (if any) among parasitic species at similar trophic levels, with no substantial shift from fundamental to realized niche in the presence of another species.

I like Price's book so much that I feel entitled to make two suggestions as to how it might be improved. First it is unfortunate that "community interaction" is treated only in the purblind Hutchinsonian sense, which studies competition to the virtual exclusion of all else. Interactions can occur horizontally in food webs — as competition or mutualism among species at very similar trophic levels — and they can occur vertically as predation and parasitism from above, or through factors such as the noxious and nutritious aspects of hosts as food from lower in the web. Perhaps this omission was made from modesty; Price has published much about community influences of natural enemies on phytophagous insects.

My second reservation concerns "coevolution", a term which here has as many references in the subject index as any other process. Price deals critically with most conceptual flabbiness in ecology and evolution, but he is soft on coevolution. For example, specialization of parasites is discussed as if it were necessarily a coevolutionary process — need it be? In another example, the inverse relationship between host breadth of agronomid flies and the diversity of their hosts' phytochemicals is treated as if it were a necessarily coevolutionary phenomenon. Again, need it be? Coevolution implies more than just the evolution of two species that live together. It implies reciprocity of influence. Evolutionary influence of host upon parasite can occur without any influence being returned, especially with benign parasites living in a non-equilibrium world.

But this is niggling. Price's book is exciting, imaginative and its influence might even be enduring, if parasitologists and eco-evolutionists find common interests as its result. □

Donald R. Strong is Associate Professor of Biology at Florida State University, Tallahassee.

## Developments in geodetic theory

William M. Kaula

*Advanced Physical Geodesy.* By H. Moritz. Pp.500. (Abacus: Tunbridge Wells, UK/International Scholarly Book Services: Oregon, 1980.) £26, \$57.

THIS treatise concerns developments in the theory of "classical" physical geodesy that have taken place since the publication of *Physical Geodesy* by W. A. Heiskanen and H. Moritz (W. H. Freeman, 1967). The implication of "classical" is that the figure and gravitational field of the Earth are considered as constant in time. The book is intended for research workers and graduate students in geodesy and gravity, and opens with a thorough introductory exposition on the background to the subject. About half the book is devoted to advanced least-squares collocation theory and one-third to the geodetic boundary-value problem. A topic not treated is the differential geometry of the gravitational field; for this *Mathematical Geodesy* by M. Hotine (US Dept of Commerce, 1969) is still the best book available.

The strengths of the book lie in the soundness of its mathematical foundations, the clarity of the writing and the authoritative tone of its discussion of modern developments in geodetic theory. Despite the rigour of the mathematics the text has an easy style, understandable to engineers and physical scientists. The authoritative tone arises naturally from Helmut Moritz being a leading contributor to the field, but work by others, such as Molodenskiy, Krarup, Bjerhammar and Sanso, has been well integrated.

To me the weaknesses of the book all appear to be in the area of least-squares collocation: firstly, an excessive simplification of gravity field properties, leading to an under-estimation of some difficulties; and secondly, a failure to take advantage of concepts and techniques developed outside geodesy.

The principal simplification is that gravity is taken to be homogeneous and isolated: a global covariance curve is taken as given, and no cross-covariance with other variables, such as topography, is considered (although accounting for topography by isostatic reduction is mentioned). However, it is in these areas that the greatest difficulties occur in applying collocation: the appropriate data selection to determine the covariance curve, and how to take into account topography as an influence on the distribution of data, as well as a correlate, and hence predictor, of gravity. Although Moritz recognizes that complete representation of a continuum like gravity requires an unlimited number of parameters, he does not present tools like singular value analysis or the resolution

matrix to select the limited parameter set which can be determined from a finite data base. The discussion of "improperly posed problems" does not bring out the idea of "trade-offs" between accuracy and resolution, and the heuristic opportunity of comparing similar inference problems in different fields is not taken.

Moritz's treatise is essential for any researcher specializing in physical geodesy. However, for the non-geodesist wishing to obtain some insight about the nature of the gravity field and the methods applied to it the 1967 text by Heiskanen and Moritz seems preferable. □

## Causal dilemmas

P.E. Bryant

*Social Interaction and Cognitive Development in Children.* By Anne-Nelly Perret-Clermont. Pp.206. (Academic: 1980.) £14.80, \$34.

NO subject is going to solve its problems until it realizes how difficult those problems are. A poignant example can be found in child psychology, which is faced with the major difficulty which it does not recognize and is certainly nowhere near to solving.

The problem is one of causes. Children's behaviour changes as they grow older, and it is easy enough to say what these changes are. But what makes them happen? What are the causes of, for example, intellectual development? Child psychologists have typically relied on quite inadequate techniques for answering this kind of question. An obvious example is their use of correlation. To find, as someone did, that the more a father talks to his children at breakfast the brighter they are, is, in child psychology, to conclude that parental chatter determines intelligence. But what about the possibility, *mutatis mutandis*, that brighter children provoke the tired parent into talking while dim children do not?

Psychologists have one other major technique for tracking the causes of development, and that is the training experiment, which also has weaknesses. These weaknesses are to be found in the work described in Perret-Clermont's book which attempts to demonstrate that social interactions in the form of discussions and arguments between children are an

important factor in causing intellectual changes.

The rationale behind the training experiment is simple. You think that social interaction is important, so you give a child a pre-test on some important cognitive skill like Piaget's conservation test, then give them a training period, and then a post-test exactly like the pre-test. If they are better on the post-test than a control group, you conclude that social interaction normally causes the development in question.

There are two difficulties, neither solved by Perret-Clermont. The first is that these positive results might be quite artificial. Many other people have done successful conservation training experiments using quite different methods. There must be at least a dozen successful ways, most of which do not involve social interaction between children. There is no way of knowing which has isolated the real cause.

Secondly, it's peculiarly difficult to get the controls right. For example we cannot say from Perret-Clermont's data whether it is social interaction with anyone or social interaction with children that is important. She does not take her effects apart. Nevertheless her work is simple and ingenious, and she presents an attractive causal hypothesis. But how are we ever to test it properly? □

## Vesicle in a basket

Ernst Ungewickell

*Coated Vesicles.* Edited by C.D. Ockleford and A. Whyte. Pp.344. (Cambridge University Press: 1980.) £40, \$90.

FOR more than 10 years, up to about 1975, the study of coated vesicles was almost exclusively the province of morphologists who early on had recognized the importance of these organelles in exo- and endocytotic processes. This state of affairs changed dramatically when B. Pearse succeeded in isolating pure vesicles in quantity, and thus made them available to biochemists. It is this latter group who will profit most from this monograph.

The volume contains contributions by representatives of a number of specialized fields, most of whom offer stimulating discussions and speculations on what are often rather fragmentary data. The 12 chapters fall into three groups: an introductory survey of the field; exploration of specific functions of the vesicles; and discussions of models aimed at describing endocytotic events at a molecular level.

The book opens with a classification of

endocytotic processes, and an evaluation of the role of coated vesicles in micropinocytosis and their comparison structurally and functionally with smooth-walled micropinocytotic vesicles. This is followed by a summary of the occurrence of coated vesicles in different species and cell types, and a discussion of the different pathways of intracellular transport.

The logical sequence of the contributions proceeds with a consideration of the coated vesicle in plant cells. Subsequent chapters describe in detail the involvement of coated vesicles in IgG transmission, their role in membrane retrieval in neurosecretory cells, and their function in vitellogenesis and secretory processes. All of these reviews are supplemented with high-quality electron micrographs showing the characteristic appearance of coated vesicles from different sources in both median and tangential sections.

Molecular aspects of receptor-mediated transport are discussed next, and models proposed by various researchers are compared. The authors of this contribution

conclude that specific protein transport is too complex a process to be described by any one of the proposed models. It is my impression that the same might be said of the models which try to explain how membranes invaginate to assume the configuration of coated vesicles, a topic which is also discussed. In the penultimate chapter, structural aspects of coated vesicles are reviewed; this reveals that surprisingly little work has been done on the structure of the major coat protein, clathrin. The book concludes with a cautious discussion of the importance of coated vesicles in medical science.

In summary, the book provides comprehensive coverage of the knowledge of coated vesicles up to the end of 1978 (a list of more recent publications appears in an appendix) and clearly indicates directions for future research. I recommend it to anyone who is new to the field or who is considering working with coated vesicles.

## Much to ponder in lipid evolution

T.W. Goodwin

*Lipids in Evolution.* By William R. Nes and W. David Nes. Pp.195. (Plenum: 1980.) \$29.50, £18.59.

THE authors of this book, *père et fils*, are clearly fascinated by the problem of relating biochemical parameters to the classical ideas on evolution. Concentrating on lipids, they have sifted through a great amount of information and bravely attempted to discern clear evolutionary patterns. A perusal of their final chapter indicates how difficult this data analysis was and how few new correlations have emerged. In almost every aspect studied, facts crop up which invalidate an emerging generalization. Indeed the authors' occasional frustrations are revealed by such comments as "The situation is made worse by the phylum Mollusca". This follows the view that as arthropods cannot synthesize sterols it would be reasonable to assume that molluscs, which from fossil records pre-date arthropods, would also not synthesize sterols; alas, "biosynthesis of sterols is a common property of molluscs".

The first four main chapters deal succinctly with dating and chronology, the palaeontological record, the origin of oxygen, and the temperature and pH problem. It is clear from the chapter on oxygen that anaerobic organisms can make some unsaturated fatty acids and isoprenoids anaerobically from acetyl-CoA. A discussion of how anaerobic

organisms make acetyl-CoA would have been most welcome, as would some comment on the quantitative aspects of acetyl-CoA, lipid and isoprenoid production in the presence and absence of oxygen in organisms such as yeast.

"Phylogenetics and Occurrence", the next chapter, is a straightforward and thorough account of lipid and sterol distribution in nature. The main conclusion is that no lipid distribution is unique to prokaryotes or to eukaryotes, and this is emphasized by the observation that the fatty acid pattern in blue-green bacteria (algae) is much closer to that of the eukaryote algae than to that of the photosynthetic bacteria.

The authors next turn to a consideration of phylogenetics and biosynthesis, paying particular attention to the important bifurcation in sterol synthesis at the point of cyclization of squalene 2,3-oxide. This clearly separates non-photosynthetic from photosynthetic organisms. In the former, the first cyclization product is lanosterol, whereas in the latter it is cycloartenol. The reason for this bifurcation is still obscure.

This is a book packed with interesting information and spiced with enjoyable speculation. It will help to broaden the outlook of conventional natural-product chemists and will give biologists much to ponder over. □

20 November 1980

# Deciding where to put nuclear plants

Even the most embittered opponents of nuclear power must be surprised at the good luck that has come their way in the past few months. First, there was the accident at Three Mile Island in March 1979, the chief casualty of which was the reputation of the US Nuclear Regulatory Agency. In the wake of the report of the Presidential Commission of Inquiry, it was inevitable that the regulatory commission would have to be reorganized and that its chairman, Dr Joseph M. Hendrie, would eventually be required to practise his talents elsewhere. In due course, President Carter nominated a new chairman (Professor Al Carnesale), but so soon before the election that his appointment to the job was legitimately blocked by the Republicans in Congress and will now, presumably, fall by the wayside. In the interregnum, the commission has been behaving with accustomed but quite alarming timorousness. The second reactor at Three Mile Island, entirely undamaged and now more fully understood than ever, is still out of service. The granting of operating licences for plants already built has proceeded at a snail's pace. Then, almost as if to ensure that no utility will be so rash as to order a nuclear plant for some time to come, the commission embarked at the end of July on a series of inquiries aimed at defining the criteria to be met by the sites proposed for nuclear plants. The outcome of this inquiry, known technically as a rulemaking procedure and thus designed to yield rules applicable throughout the United States, is naturally unforeseeable. Several years, perhaps five, may pass before putative builders of nuclear plants know where they stand. If they are wise, they will in the meantime put their capital into growing trees. That way, they will at least have something to burn.

Elsewhere than in the United States, stasis is less complete but of longer standing. In Britain, for example, it now seems likely that the Central Electricity Generating Board will be allowed to order one new nuclear plant in each of the next two years, but that 1982 will be largely given over to a public inquiry about the proposal to build a single pressurized water reactor of Westinghouse design. (The Three Mile Island reactors use pressurized water, but were built by Babcock.) As yet, the terms of reference of the inquiry (promised by Mr Tony Benn, previously Mr Anthony Wedgwood Benn, when a minister in the previous government) have not been decided. It remains to be seen whether the inquiry will be organized around a site-specific proposal or, alternatively, drawn in such a way that pressurized water reactors as such will be pronounced usable or otherwise. But only after that inquiry is complete will the same group of people embark on the more contentious job of preparing for an inquiry into the safety of full-sized fast reactors, now on the calendar for 1984.

Both the opponents of the nuclear construction industry and those who think it prudent to build more of them must surely agree that these are not ways in which decisions should be made about the future development of nuclear power. Whatever the rights and wrongs of the safety argument, procrastination cannot substitute for rational decision, although it may be responsible for decision by default. Since the problem of winning public acceptance, or at least of creating a sense that justice has been done, applies to other kinds of technological enterprises than the construction of nuclear power stations, it is obviously important that better mechanisms should be devised.

The regulation of nuclear power plants in the United States has been a controversial issue for the best part of twenty years. To begin with, the Atomic Energy Commission was both the sponsor of nuclear power and the licensing authority. Understandably,

and rightly, the two functions were separated a decade ago. Again rightly, the Nuclear Regulatory Commission is an independent body whose members are appointed by the president of the day for fixed terms, and who are collectively responsible to Congress and not the Administration for the proper regulation of nuclear safety. Like other regulatory agencies, the Federal Communications Commission for example, the Nuclear Regulatory Commission enjoys a kind of delegated authority to make rules which elsewhere would have the status of laws. It is empowered to make generic rules applying, say, to all reactors of a specific type, and also particular rules, as on the licensing for operation of a particular reactor. Other government agencies are powerless to influence decisions by the commissions, but those who dissent can appeal to the courts. Such appeals have been one of the most frequent means of impeding the construction of nuclear plants in the United States.

The British system is at the other end of the regulatory spectrum. Broadly speaking, all new industrial developments are subject to planning legislation. Applications for planning consent are first submitted to the lowest planning authority in the hierarchy, a county council for example. Necessarily, they are site-specific. One applicant may want to build an abattoir at the end of some village high street, another (invariably a nationalized industry) a nuclear power station on an estuary. The planning legislation provides that the Secretary of State at the Department of the Environment may order a public inquiry if either the proposers or the opponents of some innovation are aggrieved, or if he and his officials consider that the issue has wider importance. The planning legislation also allows for the appointment of commissions of inquiry to determine generic questions — are motorways, or nuclear power stations, or fast reactors, really necessary, for example? But this procedure has not so far been used, no doubt for fear of creating precedents.

Both the British and the American systems are intended to serve similar ends — to allow objectors, especially disappointed objectors, a proper sense that their objections have been fully heard, but also to give the public at large a sense that important questions have been properly examined. That, at least, is the theory. The reality is usually less than satisfying. Private objectors are usually less well equipped, at least financially, to put their case to government inspectors. In the United States, the Internal Revenue Service allows charitable foundations to contribute to the cost of putting objections to a public hearing. In Britain, where this is not permitted, the government might think it worthwhile making some funds available for objectors to important schemes. (Inspectors at present have a right to penalize frivolous objectors with an order to pay costs, but that is hardly the same thing.) A more serious difficulty under British planning law is that objectors to a novel scheme have only restricted rights to argue that the objective of a new plant might be better achieved by siting it somewhere else.

These, however, are relatively minor difficulties. The most serious objection to both the British and the American systems for deciding whether and, if so, where nuclear power stations should be built is that both of them are inevitably subject to political forces in the broadest sense, and are thus far from being objective. In Britain, the more fuss that can be made about a proposal to build a nuclear power station, the greater the chance that there will be a public inquiry. All nuclear plants so far built have been brought into the world with ceremonies of this kind. No minister with an eye to re-election would think otherwise. In the United

States, similar pressures affect the Nuclear Regulatory Commission, whose reputation would quickly sink still further if it were often defeated in the courts on the grounds of not having been scrupulous about due process. And at inquiries of both kinds, there is nothing to prevent the most local objectors from raising the biggest questions that come to mind. Does the country need nuclear power anyway? Is this kind of reactor safe? Why should Blanksville or Dashby be the first prisoner of the plutonium economy, as it is called? In the United States, these pressures have led to a quite absurd proliferation of the subjects on which the Nuclear Regulatory Commission is holding public hearings. The inevitable result is more prevarication, more delay.

As things are, the only seemly escape from the dilemma is to devise a means of limiting the scope of public hearings without limiting the right of objectors to object. On the construction of

nuclear plants, it is pointless that public hearings should rehash questions of whether nuclear power as such is necessary, or economic, or likely to be overtaken by solar power. Both Britain and the United States have elected governments which reckon to include such questions in the fields of their competence. Similarly, there are questions about the relative (not absolute) safety of different reactor types which are generic in character, and which could (and should) be argued out once and for all. Questions of siting, on the other hand, are essentially local or regional matters (which is not to imply that they should not be disputed nationally). But it should be open to objectors to argue that some other site would be more suitable. The British log-jam of nuclear inquiries will not be broken until 1984. Is there a chance that Mr Reagan will be able to move more quickly in the United States when January has come?

## Scope for European collaboration?

The famous conjuring trick in which the Cheshire Cat was made to disappear but to leave its smile behind is no doubt the envy of the professionals who still work the music-halls. The European Science Foundation, which held its annual assembly last week in Strasbourg (see page 204), is trying to do much the same. Its members are research councils and learned academies from most Western European nations, all of them supported financially by their national governments. Their membership of the foundation is voluntary, as are their contributions to the special research projects which are from time to time devised. It is just as if they belonged to a club for organizations like themselves and, like the members of other respectable clubs, they spend some time each year considering what the fees for membership should be. The trick, which has worked well in the past six years, lies in the foundation's insistence that it is strictly a non-governmental organization, free (if its members agree) to criticize developments at which its members' paymaster-governments may have connived. This is the spirit in which the European Space Agency has been taken to task in the past two years for the inadequacy of its plans for launching scientific satellites. On other occasions, the foundation assumes the freedom to put pressure on the same governments to act in some specific way — to build a synchrotron radiation source, for example. The hapless governments see the smile (or the grimace) but appear not to recognize the body.

That, fortunately, has been the foundation's experience so far. Part of the explanation is that it has been run on a kind of shoestring. The members' contributions to the foundation are such modest proportions of the national public funds they receive that even the most hyper-touchy governments would feel foolish if they reacted against the foundation's members' modest show of independence. But will it be the same if the foundation grows, becoming less inconspicuous in the process? That, inevitably, must be one of the concerns of those who now think that the time has come for modest growth. The time has come to ask what the foundation is for, and what it might be for. For the past few months, a domestic think-tank has been brooding on the same two questions.

The bread and butter of the foundation's business is easily justified. Plainly it is useful that there should be an umbrella under which organizations with a responsibility for the support of research and scholarships can meet from time to time, even if they talk only about administrative matters such as how to adjust research grants for inflation. In principle, it is also plainly beneficial that there should be some mechanism for tackling research problems of common European concern. European taxonomy is an obvious candidate. So too was the project to mount a coordinated study of the problems of preserving mediaeval stained glass, but that fell foul of the chauvinistic quarrelsomeness of the experts in the field. Unexpectedly, but not surprisingly, most enthusiasm seems to have been generated by the common interest of European scholars in external problems — the literature of China and Byzantine history, for example.

Collaborative research programmes within Europe itself seem more easily arranged in the social than the hard sciences — partly because of the costs involved but also because international comparisons come more naturally to mind in the social sciences; in the hard sciences, inevitably, everything is everywhere the same. Yet there is obviously plenty of scope for further collaborative research. The geophysicists have for example an ambition to mount a seismic traverse of Europe from north to south, reaching into North Africa, that could probably be mounted within the necessarily limited time-scale of *ad hoc* voluntary contributions by the member organizations. The plan to build a source of synchrotron radiation would, by contrast, require a continuing commitment of funds, and thus endanger the loyalty of some members or the compliance of their governments. The strategy the foundation has pursued — to interest governments in the idea — is thus the only practicable way of seeing such a machine built.

So where does the foundation go from here? For the time being, there are grounds for being cautious. Inevitably, in only six years, the foundation has comparatively little to show for the trouble it has been taking. Ultimately — and there should not be long to wait — it will be judged by the quality of its collaborative research. If the outcome is worthwhile, the result should be a rash of other projects crying out for supplementary contributions. In the meantime, however, there are other tasks on which the foundation could busy itself. The recent study on the mobility of academic scientists within the European Community (see *Nature* 23 October) made much of the lack of movement between European countries (as distinct from the now common journeys across the Atlantic). As things are, several of the foundation's committees organize research workshops, symposia and the like in their narrow fields, but the scale of such activities within Europe is nothing like enough, in spite of the efforts of the European Molecular Biology Organization and the federations of specialist scientific societies that have sprung up. More ambitiously, there is a case for asking the foundation to share in the administration of the European exchange fellowship scheme, so far in the hands of national academies but much in need of escaping from the strictly bilateral basis on which it was set up eight years ago. (With a little luck, an international organization might even be able to tap supranational sources of funds, the European Community for example.) Finally, there are some crucial housekeeping tasks not at present being done (or done well) for European science. There is, for example, a crying need for a directory showing who does what in European research, some means of knowing who is where and a systematic way of telling which national organizations spend how much. Coherently compiled statistics of the working (and output) of European university systems would be a great boon. If one immediate objective is to ensure that the smile remains visible and the rest of the animal inconspicuous, this must surely be the best way forward.

# Backlash against DNA ventures?

## More thoughts at Harvard on business link

### Washington

Harvard University's announcement that it is considering setting up a company to exploit the results of its recombinant DNA research (*Nature* 30 October, p.769) has provoked a backlash on university campuses that may lead Harvard to drop the idea. The company is seen by some as a threat to academic freedom.

University administrators have, in general, welcomed the Harvard proposal, particularly since many of them are already discussing similar ideas of their own but have not yet made them public.

Yet at the same universities both scientific and non-scientific faculty members have warned of the dangers of steering basic research towards commercial objectives, suggesting that there are elements in the Harvard proposal which make it qualitatively different from more conventional arrangements for linking university research and its industrial applications.

One group which has taken up the issue is the academic freedom committee of the American Civil Liberties Union (ACLU). The committee has set up a subcommittee to draft a possible policy statement for ACLU to consider on guidelines to cover relationships between universities and industry.

"I do not think that you can divorce the universities from industry, but the contribution that we can make is to set guidelines down for the future, for which we feel both faculty and administrators would be appreciative, as they have been in the past on issues such as military research", Dr Bernard Belush, chairman of the academic freedom committee, said last week.

Other universities considering new ways to profit from their research are going through similar debates to that at Harvard, where more than half the faculty members were reported by the *Wall Street Journal* to have told Harvard president Derek Bok that they were opposed to the idea.

At Yale University in New Haven, for example, the faculty has asked for a revision of proposals which have been put to it for encouraging greater links with industry, and has expanded the committee looking at these proposals — which might, as at Harvard, include the idea of setting up a research development company — to include more non-scientists, who had been among the critics of the original proposal.

• A similar debate is expected at the

University of Michigan at Ann Arbor, where there is a proposal to link up with a local pharmaceutical company, Warner Lambert, to provide training facilities for the company's research personnel.

Dr Charles Overberger, vice-president for research at Ann Arbor, said last week that although there were no firm plans to set up a separate company, talks had been held with a venture capitalist, Mr Herbert Doan, an ex-chairman of the Dow Chemical Company.

At Stanford University in California, where much of the original recombinant DNA research was carried out, the debate is already at an advanced stage. A proposal similar to Harvard's was made several years ago that the university should become more directly involved as an investor in exploiting its research results, rather than merely offering patent rights.

The proposal was, however, shelved after strong opposition from several faculty members, including Professor Paul Berg of the university medical school's biochemistry department.

Rather than getting directly involved, the department is now setting up an industrial affiliates programme under which companies which sign up will be able to send representatives to one seminar a year on the department's work, to receive one visit a year from a faculty member to discuss the company's research and to send a representative to Stanford to discuss this research with faculty members.

In return, the company will give \$12,000

annually to the university, which the department hopes will be used to support junior research posts. Fifteen companies — including Cetus, Genentech and several major pharmaceutical firms — have already signed up, and the department has a growing waiting list.

Dr Donald Kennedy, who took over as Stanford's president earlier this year after spending four years as head of the Food and Drug Administration in Washington, admits that the new commercial pressures on biological research have thrown up a variety of problems which biomedical researchers have never previously had to face. "Quite possibly it is time for some leadership to be sought or to well up in universities on this point as it has done on other points in the discussion of the social responsibilities of scientists", says Dr Kennedy. "Perhaps it is time for another Asilomar, but it ought to come from the people who are doing the science."

At Harvard, university officials insist that they have gone to considerable lengths to prevent any potential conflict of interests between the academic goals of the institution and its investment policies. For example, no university administrators would be directly involved in investment decisions taken by the new company, which would be completely separate from the university. Although the university would be a minority shareholder, it would not be investing any of its endowment, since the shares would be provided in return for access to research results.

## Science Research Council comes clean

The UK Science Research Council (SRC), which could not say (*see Nature* 13 October) how many research grants were outstanding at the end of the last financial year because of a computer oversight, has now produced reliable figures. According to the revised account, 3,933 grants were current on 31 March 1980, of a total value of £120.5 million. This is an increase in number of 15 per cent and in value of 34 per cent over the previous year.

The increase is still substantial and unplanned. Indeed, it is the first major increase of grant allocations for many years. It is only partly accounted for by the "equipment round", a £7.5 million handout for major items of equipment in universities which took place in the summer of 1979.

Last week the Department of Education and Science (DES) came to SRC's aid, allowing the council to transfer £5.7 million of its savings on foreign subscriptions, due to the strong pound, to other accounts. SRC can thus pay for some of this year's increased expenditure on grants. Even so, the council was due this week to seek another £2 million of savings on current spending, on top of £4 million

worth of cuts already made.

SRC will therefore scrape through the current financial year without requiring extra finance from DES — but the year to follow (April 1981 to March 1982) looks increasingly bleak. The pound seems unlikely to rise further against the European currencies in which foreign subscriptions are mostly paid, and indeed it may fall if interest rates in London money markets are reduced. Thus the £5.7 million found on exchange rates this year may vanish or even become negative next year, while the grant commitment will remain obstinately high.

Next year, accordingly, the council will have to seek an increase in its funding above the £175.3 million included in the provisional 1980 five-year forward look, to pay for its support for the universities last year. There is no reason to suppose that the other dependants of the Advisory Board for the Research Councils will be sympathetic. The council's finances are, however, unlikely to be seriously affected if it is required to refund the price of its annual report (HMSO, £7.50) to purchasers complaining that the figures it contains are wrong.

Robert Walgate

Whether this will be sufficient to answer the critics remains uncertain. While scientists were voicing their fears about academic freedom, several investment houses were saying in public last week that they thought it was a bad thing for a university to get involved in commercial operations. Dr Bok's announcement about whether the university intends to go ahead with plans to set up the new company is therefore awaited with great interest.

David Dickson

## European science

### Foundation stones

#### Strasbourg

The European Science Foundation ended its annual general assembly here last week (13 November) in a vaguely hesitant frame of mind. Unlike previous assemblies, this was less a general amplification of the enthusiasm for international collaboration of member organizations (now 47 research councils and learned academies from 18 countries) than a reluctant recognition that the next six years may be more difficult than the past — and first — six.

Part of the hesitancy stems from changes of personnel. Lord Flowers, rector of Imperial College, London, and president of the foundation for the past six years, handed over at this year's assembly to Professor H. Curien, director of the CNRS (Centre National d'Etudes Spatiales) in Paris, while Dr. John Goormaghtigh succeeded Dr Friedrich Schneider as secretary-general only a year ago. But the member organizations seem also to be preoccupied with domestic funding problems and thus less able to think expansively than in recent years.

Several of the foundation's recent initiatives appear also to be at critical, even

anxious, stages. Thus the development of a plan for what is called the European Synchrotron Radiation Facility, on which a foundation study group has been working for the past three years, is in the air. At the general assembly in 1979, the retiring secretary-general, Dr Schneider, was asked to spend a year sounding out European governments on their willingness to contribute towards the cost of the machine, estimated at something of the order of \$100 million.

Dr Schneider appears to have found this a disappointing year. Potential contributors to the cost of the machine have taken the view that haste might jeopardize eventual construction. Some governments also appear to be suspicious that the foundation is usurping their role of making treaties among themselves for multinational projects. The study group (under Professor Y. Farge of Orsay) will, nevertheless, remain in being during 1981, concentrating on the further refinement of its proposals.

The foundation is also despondent about the prospects for space research in Europe. A year ago, one of the foundation's published reports took the European Space Agency to task for the degree to which its then programme was biased to the development of the Ariane launching system, to the detriment of plans for launching scientific satellites. At this assembly, delegates were told that there has been no substantial improvement. Plans for launching European scientific satellites are so sparse that scientists who are members of space research groups in Europe may have to wait about five to seven years between successive experiments. Professor Curien told the assembly that this might be inevitable in studies of "the reproduction of the elephant, or of silviculture", but that it was

an entirely artificial circumstance in space research.

The foundation is not, however, entirely frustrated. Its programme on polymer structure is going well (see box), while the assembly agreed to launch a number of new projects in the social sciences while continuing most of its past successes, the programme of training in "brain and behavioural research", for example.

On more general questions, the foundation has decided to keep in being the Liaison Committee on Recombinant DNA Research even though, according to a statement from the committee, the need for attempts to coordinate containment guidelines has melted away. The focus of anxiety has moved to what are called "second generation" issues, including the pace and the manner in which recombinant DNA techniques are being commercialized with the possible consequential risks to academic research. Dr Philip Handler, president of the US National Academy of Sciences, said in his invited address to the assembly that academics forming commercial links with DNA companies were "creating a great deal of difficulty for the others working in this field".

The foundation has also issued a statement asking that national governments planning new legislation on the confidentiality of computerized data banks should also bear in mind the value of such data, suitably shorn of identification, for the research community.

The assembly approved the foundation's budget for 1981, which exceeds FF5 million for the first time, and which does not include the cost of the special research projects (called "additional activities") to which member organizations contribute on a voluntary basis.

Lord Flowers estimated, in his final address to the assembly, that the total expenditure on the foundation's activities amounted to less than 0.1 per cent of the budgets of member organizations, and hoped that the next six years would see a tenfold increase in this proportion in the next six years, as well as a further extension of the foundation's sphere of interest. The academy of Finland was admitted as a full member of the foundation with effect from 1981.

## Fusion research

### Livermore looks up

#### Washington

After a period of considerable uncertainty, scientists in the two main fusion energy programmes at the US Department of Energy's Lawrence Livermore Laboratory in California are confident that recent technical advances are given a significant boost to the chances of being able to exploit nuclear fusion as a commercial source of power.

In the magnetic confinement programme, successful tests with so-called tandem mirrors, which could be used to

## Something ventured, something done

Both the new research projects approved by the 1980 assembly are in the social sciences. One, under the rubric of "comparative law", and to which ten countries have agreed to contribute, includes an attempt to define and compare the medical responsibility within Europe. The study will include the responsibilities of physicians and drug firms towards patients and the influence of medical insurance on the behaviour of physicians. There is also to be a European study of procedures for summary jurisdiction in civil and other courts.

The social scientists are preoccupied with migration and language, and have won approval for two other research projects — the problems of language acquisition by adult migrants within Europe (of whom there are estimated to be 11 million) and a series of research workshops on the human and cultural aspects of migration within Europe.

There is also to be a one-year study of

problems of technical innovation and social change, chiefly so as to identify fields in which coordination by the foundation might be beneficial.

Continuing projects that appear to be flourishing, or nearing fruition, include:

- *Chinese studies.* A handbook of Chinese literature in the period 1900-49 is nearing completion, while a descriptive catalogue of the body of fifteenth century Chinese literature known as the *Tao-Tsang* is well under way.

- *Brain and behaviour research.* The foundation plans to spend in 1981 a total of FF1.3 million on this programme of training awards and travel grants.

- *Taxonomy.* The *ad hoc* group on European taxonomy is to be disbanded, and its final report published in March next year. The draft report claims to have made substantial progress towards understanding the difficulties of coordinating European taxonomic nomenclature.

"plug" the ends of a solenoid containing plasma, have led to the decision to include the mirror devices in the Mirror Fusion Test Facility (MFTF) at present under construction. Work is already under way on plans for a new, larger machine, tentatively referred to as the Tandem Mirror Next Step (TMNS), which could become a serious rival to the tokamak design.

The programme based on inertial confinement techniques is also looking well. Recent experimental data indicate that solid state lasers made from vanadium-doped magnesium fluoride crystals have characteristics, high energy efficiency chief among them, which may overcome the difficulties experienced with the use of more conventional solid state lasers to ignite a deuterium-tritium pellet.

The tandem mirror is a device first proposed in 1976, when experimenters were experiencing considerable difficulty in preventing plasma from escaping its containing magnets along field lines which are open rather than closed (as they are in a tokamak). Its ancient ancestor is the machine called DCX, developed at the Oak Ridge National Laboratory in the 1950s.

Proposed simultaneously by Ken Fowler and Grant Morgan at the Livermore Laboratory, and Soviet scientists at Novosibirsk, the mirror acts by using two magnets to contain a plasma in an electrostatic potential well, the plasma being positively charged because electrons are able to escape faster than protons.

Small-scale experiments were carried out by research workers at the University of Tsukuba in Japan last year, demonstrating that, in principle, a tandem mirror designed to contain a plasma in this way does create the predicted potential well.

Subsequently, Livermore scientists have concluded a series of experiments on the tandem magnet experiment (TMX) in which they have been able to demonstrate that a solenoid with such plugs at each end can contain a heated plasma at a mean energy of 0.2 keV per atom, as compared with 13 keV within the end mirrors.

The attraction of a commercial fusion reactor based on this design would not only be the easier design tasks presented by a straight solenoid rather than a toroidal tokamak, but also that, once the end plugs have been produced to the tandem mirror design, the length of the solenoid between them can be adjusted at will to provide the power characteristics required.

The US Congress has already been sufficiently impressed to approve substantially increased funding for the MFTF now being built.

Its success or otherwise will determine whether the department should proceed to the next logical step, the TMNS. Livermore scientists feel that magnetic mirror designs could catch up with tokamak technology, the most likely design for a Fusion Energy Device (FED), and which the department hopes to build over five to ten years.

• Meanwhile, those working on the

inertial confinement techniques are hoping that the promise of vanadium-doped magnesium fluoride lasers may overcome doubts about the ultimate potential of solid state lasers as fusion drivers.

Most of the research so far has been done on glass lasers, initially with red light and more recently, following the development of techniques for doubling the wavelength, with green and blue light which has a greater ability to focus energy on a small deuterium-tritium pellet.

Preliminary evidence suggests that, in contrast with the conventional krypton fluoride laser, which only has an efficiency of between 5 and 7 per cent, a V:MgF<sub>2</sub> solid state laser would have an efficiency of between 5 and 10 per cent. With other advantages, this would help to reduce the cost of electricity from an estimated \$300 million to \$100 million per megajoule.

Livermore scientists are now carrying out further experiments to determine whether crystals with such characteristics can in fact be grown for use in lasers. If so, solid state lasers will remain a serious contender in the fusion stakes.

David Dickson

## Radioactive waste

# Brussels helps

The parallel research programmes of the European Economic Community (EEC) and Canada on the storage of radioactive waste are to be linked. A five-year agreement was signed in Brussels on 3 November between the European Atomic Energy Community (Euratom) and Atomic Energy of Canada Ltd. It follows on from the original Euratom/Canada agreement of 1959.

The new agreement relates particularly to the evaluation of the environmental impact of the storage of wastes in hard rocks, and to collecting data on the development of safe waste storage systems. There has already been considerable cooperation between scientists in these fields, so the agreement puts this on a more formal basis and opens the way for even closer cooperation.

Initially the agreement will lead to exchanges of technical information, organization of joint scientific meetings, and exchange visits of scientists between Canadian and European laboratories.

The agreement is the first in this field between the community and an outside country. It is likely to be a pointer to a trend towards more international cooperation, and the United States is already showing interest in closer cooperation with the EEC.

The community's own research programme was unveiled with a great fanfare in Luxembourg in May this year. The community's contribution, US\$130 million, is planned to extend over four years. Of the total, \$100 million will be contributed on a fifty-fifty basis to national research programmes, while \$30 million will be spent at the joint research

centre at Ispra.

Research on the disposal of high-level wastes is well advanced in France, West Germany and the United Kingdom. In each case, the objective is to embody high-level radioactive wastes in some solid form — France and the United Kingdom are chiefly interested in vitreous solids, while West German studies have also taken account of bitumen-like materials.

In several member states, investigations are also under way to identify disposal sites for solidified radioactive waste. France and the United Kingdom are exploring granite formations, West Germany salt formations while Belgium and Italy are concentrating on siliceous (clay) formations.

Jasper Becker

## Waste disposal

# UK goes French

British Nuclear Fuels Ltd (BNFL) whispered last week its intention to use the French AVM process for vitrifying highly active nuclear waste emerging from the Windscale reprocessing plant, thus bypassing the British "Harvest" vitrification research programme which has been under way at Harwell. There was no official announcement by BNFL: rather, the news emerged during a routine meeting of the Windscale local liaison committee, a group convened to keep the local community aware of developments at the plant. The leak was intentional, and confirmed rumours that BNFL had chosen AVM some time before.

A full commercial agreement between BNFL and Cogema, the French company which developed AVM, has not yet been reached, and if Cogema's price is too high the deal may still fail through. As presently envisaged, it would entail constructing an AVM (*atelier de vitrification à Marcoule*) plant at Windscale in the late 1980s, under licence from Cogema.

BNFL will not say at this stage why it has chosen AVM, though the reasons are not far to seek. Both the French and the British began work on vitrification in the late 1950s but work halted in Britain in 1966 when the principle had been demonstrated. (It was felt at the time that it would be possible to store liquid high active waste indefinitely in tanks.) Political pressure led to the setting up of the Harvest programme (Harwell vitrification engineering study) in 1973, but by then Cogema had established a seven-year technological lead.

While the Harvest team at Harwell is even now using only simulated nuclear waste, a plant called PIVER was built at Marcoule eleven years ago to handle the real stuff in commercial quantities. PIVER ran from 1969 to 1973, and produced 12 tonnes of vitrified waste containing 5 million curies of activity — roughly speaking the arisings of a 1 GW nuclear power plant working over the same period.

PIVER was a batch process, like

Product of Harvest

Harwell's Harvest; its successor AVM, incorporated in a plant at Marcoule which began operation two years ago, is continuous, allowing — it is claimed — a roughly twofold saving in capital equipment costs for the same waste throughput. The AVM plant is remotely controlled, and is constructed from units none larger than 500 kg for ease of handling and replacement. The French process is thus many years ahead of its British — or any — rival.

Nevertheless there is still a question mark over BNFL's haste to conclude an agreement with Cogema. The decision to abandon Harvest is as much a political as a commercial one. At present, about 1,000 m<sup>3</sup> of high active waste is stored in liquid form in tanks at Windscale, and BNFL still considers that it could remain in these tanks, or new ones, for some decades. Further tanks could be built for the oncoming nuclear power programme, but it is felt that public opposition to the programme — which will be expressed in the promised PWR enquiry — may be less if vitrification work is seen to be progressing apace. The argument, however, turns a

blind eye to local opposition to drilling tests, to find sites for future long-term disposal of the glass.

At Harwell, Dr Ron Flowers, who heads the chemical technology division that developed Harvest, says that he expects to close work on the project by next March, once experiments are completed and final publications prepared. Loss of the Harvest contract — which was paid for by BNFL, the Central Electricity Generating Board, and the Department of the Environment — will not be a serious blow to the division, he says.

Robert Walgate

### Soviet dissidents

## Another taken

Viktor Brailovskii, the Moscow Jewish mathematician who regularly hosts the Sunday seminars for *refusnik* scientists, was arrested last week, reportedly under Article 109/1 of the Criminal Code which deals with slander of the Soviet Union and the socialist system and the circulation of "publications known to be false".

News of the arrest, coming shortly after the opening of the Madrid review conference on implementation of the Helsinki Final Act, has caused consternation among his colleagues and friends abroad, who see it not only as a threat to Brailovskii himself, but also an adverse omen for Soviet intentions regarding "Basket 3" of the Final Act, which deals with human rights.

Brailovskii, who is a specialist in cybernetics and computer programming, first applied to emigrate to Israel in 1972. His application was refused, and he was then dismissed from his academic post. Since then, he has had no chance of obtaining any job in science.

It was to help such "*refusnik*" scientists keep up their academic interests that the Sunday seminars were founded in 1973 by Aleksandr Voronel'. When Voronel' and then his successor as seminar leader Mark Azbel' finally managed to emigrate, Brailovskii and his wife Irina (also a mathematician) became hosts to the seminar.

A recent Western visitor reports that in spite of a total lack of access to scientific facilities, including journals, the standard of discussion remains high, and there is considerable participation by young Jewish scientists who are attempting to carry out some kind of postgraduate study on their own.

A frequent visitor to the seminar, the traveller said, is Evgenii Chudnovskii of Khar'kov — a city where the refusal rate has always been particularly high — who is now trying to organize what he calls a "Jewish university" for young *refusniks*.

According to Mrs Brailovskaya, the seminars will continue in spite of her husband's arrest. The citation of Article 109/1 presumably refers to the *samizdat* journal *Jews in the USSR*, of which

Brailovskii was for a time editor. However, this journal ceased publication in summer 1979, and the long delay before an accusation on this charge seems unreasonable.

### German science

## New man arrives

Germany has a new Minister for Science and Technology: 43-year-old Andreas von Bülow, who since 1976 has been Parliamentary Undersecretary of State for Defence. The Bundesministerium für Forschung und Technologie BMFT is Dr von Bülow's first ministerial appointment — as it was for his predecessor, Dr Volker Hauff. Dr Hauff now moves on to the Ministry of Transport, which is considered to be a more senior political appointment.

Dr von Bülow has had no time yet to form his policies for the BMFT, but he is expected to lean more to the right of his party, the SPD, than Dr Hauff, who attempted to use the ministry as an

instrument of economic policy (through its involvement in technology). But Dr Hauff — after seven years in some capacity at the BMFT — was said to be becoming impatient at the inertia of the research community, and particularly the big science institutions like the Karlsruhe nuclear research centre and others which had grouped themselves into a powerful lobby, the Arbeitsgemeinschaft der Grossforschungseinrichtungen (AGF). It remains to be seen what Dr von Bülow will do with that. His ministry plays a coordinating role in German science, akin to that of the Delegation Générale à Recherche Scientifique et Technique in France; but it controls a much larger budget — around DM 6 billion (£1.25 billion). This is the bulk of the federal finance applied to R&D Germany, another DM 3 billion or so being under the direct control of other ministries. (A further DM 6 billion is spent by the state governments, mostly to support universities, and DM 16 billion by industry.) The BMFT, along with the state governments, supports the institutions of the AGF, the Max Planck Gesellschaft (which runs the Max Planck institutes), the Deutsches

### The differences

High active waste emerges as a liquid from the reprocessing of spent fuel: it is a solution in concentrated nitric acid of the nitrates of actinides and fission products. The object of vitrification is to immobilize the radioactive elements. In the Harvest process, which is only at the pilot stage, a simulated waste is mixed with the components of a borosilicate glass, poured into a tube, evaporated and glassified in one step in a furnace. The tube becomes the primary container for the glass. The process is a batch process. In the AVM technique, a high active liquid stream is evaporated and calcined (converted to oxides) in a rotary calciner. Each hour, the calciner accepts 40 litres of liquid waste and converts it to brown granules, which leave the furnace continuously. The granules are mixed with borosilicates and melted in a stainless steel container. Every eight hours, the container pours out 140 kg of glassified waste into storage drums. The drums are moved out, lids are welded on, and the drums moved to storage caves — all automatically.

Forschungs-gemeinschaft (which funds research projects in the universities), the Fraunhofer Gesellschaft (the equivalent of Max Planck, but for applied science), and other science promotion bodies. The ministry also promotes research and innovation in industry through a number of mechanisms.

## Indian environment

### Shandi inverted

#### Bangalore

Mrs Gandhi's new government seems to have taken the environment to heart, to judge from the spate of decisions since the election at the beginning of the year and the appearance of the environment in the newly published Sixth Development Plan.

In recent years, environmental abuse in India has increased alarmingly. Urbanization, industrialization and river pollution have all conspired to make a mockery of the United Nation's slogan of "development without destruction" in a country renowned for its religious regard for the variety and greatness of nature. The repercussions of this indiscriminate assault on the ecological system are telling:

Barren hill

landslides and flash floods in the Himalayan foothills have caused heavy loss of human lives and property, top-soil erosion and growing aridity in the Ganges plains have had severe consequences for agriculture.

Successive Indian governments during the past 30 years have shown little awareness of the cardinal importance of environmental planning in developmental activities. It was only after Mrs Gandhi's return to power in early 1980 that the environment assumed significance.

Since then, work on the controversial Silent Valley hydroelectric project in the tropical rain forests of southern India has been suspended and the rate of deforestation in the Himalayan foothills has been

greatly reduced.

It is a measure of the growing public ecological awareness that the last session of the Indian parliament witnessed perhaps one of the liveliest debates on the environment. Intervening in the debate, Mrs Gandhi made it clear that the nation must not repeat its earlier mistake of allowing industrial projects, despite their economic importance, to damage the delicate environmental web.

During the debate, a ruling party member, Dr Karan Singh, expressed shock over the "ruthless denudation of Himalayan vegetation by corrupt politicians, corrupt officials and corrupt contractors". He further lamented that even the Ganges had now been contaminated.

Another member, Mr Digvijaya Narain Singh, said that, as a result of top-soil erosion, 90 million hectares — equal to 28 per cent of the total land area — had now become practically barren. He urged that there should be a separate department concerned with land use, forestry, wild life, pollution control, marine ecosystems and the promotion of environmental protection.

This suggestion seems likely to be incorporated into the government's long-term environmental strategy, which will be based on the recommendations of a 14-member committee set up to suggest legislative measures and administrative machinery for environmental protection. The committee, headed by Mr Narayan Dutt Tiwari, deputy chairman of the Planning Commission, has come out strongly in favour of immediate coordinated action at both central and state levels to give environmental protection a crucial place in the country's programmes and policies.

The Indian government is also contemplating introducing a bill on the prevention of air pollution in which would be based on proposals put forward by an expert committee appointed in 1978 to study air and water pollution in the urban areas of India. Air pollution has become a major health hazard in cities such as Bombay, where the content of carbon dioxide in the atmosphere has been increasing by 4.2 per cent a year due to the 65 tonnes of dust ejected into the air each day by industry and vehicles.

B. Radhakrishna Rao

## Nuclear fallout

### Weapons are worst

States with substantial nuclear industries should do everything they can to avoid strategic nuclear attacks. That is one of the inevitably ironical conclusions of a study of catastrophic nuclear radiation releases by Steve Fetter and Kosta Tsipis of the Program in Science and Technology for International Security at Massachusetts Institute of Technology.

The chief objective of the study has been to compare the long-term consequences of nuclear weapons exploded in the air and on the ground, catastrophic releases of radioactivity in reactor accidents and the explosion of nuclear weapons on or near nuclear reactors or reprocessing plants. Although it is recognized that the immediate effects of weapons explosions as distinct from reactor accidents will consist largely of the death of people and the destruction of property, the calculations are aimed at estimating the area of surrounding land that will be unfit for human habitation after an explosion or some other catastrophe.

For the purposes of the calculation, the authors assume that half the energy released in a one-megaton thermonuclear explosion is provided by fusion reactions and the remainder by the fission induced in a surrounding blanket of uranium-238. For weapons burst in the atmosphere, radioactivity from the fission of uranium-238 will be the sole source of long-term contamination, and much of its debris will be distributed by stratospheric processes.

The areas rendered uninhabitable after a nuclear explosion are sensitively dependent on the criteria used for deciding what doses of radioactivity are acceptable. For a ground burst weapon whose debris is spread in the lower atmosphere by a 15-mile per hour wind, the authors calculate that 5,700 square miles of land would be uninhabitable for a year if doses greater than 2 rem per year were considered unacceptable, but that fewer than 50 square miles would be uninhabitable a year after the explosion if 100 rem per year were taken as the cut-off dose.

Inevitably the consequences of the explosion of a nuclear weapon on or near a reactor are more startling. Using the somewhat stringent criterion of a limiting dose of 2 rem per year, the authors conclude that 50,000 square miles of land would be uninhabitable for a year. The destruction of a waste storage facility would have still more horrendous consequences, putting 64,000 square miles out of action for a year. By comparison, the report concludes, the consequences of a reactor melt-down and a subsequent release of radioactivity would be comparatively small, sterilizing only 900 square miles for a period of one year.

The obvious but impractical import of these calculations, Fetter and Tsipis say, is that countries seeking to avoid devastating damage from distributed radioactivity in a nuclear war should either dispense with a nuclear industry or build reactors and reprocessing plants underground. They also point out that because the permanent damage done by a single nuclear weapon detonated on the ground is so much greater than that in the "worst conceivable nuclear reactor accident", it is hard to understand the greater anxiety of the general public about the risks of civil nuclear accidents than with the consequences of nuclear war.

## CORRESPONDENCE

## Museum of errors

SIR — Two years ago (*Nature* 275, 683; 1978), I questioned the wisdom of what is happening at the Natural History Museum in South Kensington. If a national museum is concerned with aspects of social engineering, by promoting concepts that happen to be current in the present climate of opinion, are there not sinister implications? I was especially alarmed by the museum's new exhibition scheme, and asked that sufficient pressure should be brought to bear to "curb the activities of the Public Services Department and to ensure the survival of the museum's reputation for scholarship in its public galleries".

Since then, time has passed. It is no longer a question of raising the alarm but simply of reporting what has already happened.

Two areas of the museum's work have already succumbed: dinosaurs in 1979 and fossil man in 1980. Both the new exhibits are simply vehicles for the promotion of a system of working out relationships known as cladistics. The accompanying booklets *Dinosaurs and their living relatives* (1979) and *Man's place in evolution* (1980) explain with startling clarity the essence of cladistics. In both books the fundamental assumptions are spelt out unequivocally. "First we assume that new species arise when one species splits into two. This assumption allows us to test the relationship we suggest, because it means that every species must have a closest relative. Second we assume that none of the species we are considering is the ancestor of any of the others." It is axiomatic, therefore, that no species in the fossil record can be considered ancestral to any other nor can one species evolve directly into another.

With regard to both dinosaurs and fossil man, it is evident that the application of cladistics is quite inappropriate. The well attested sequence of human fossils representing samples of succeeding populations has, until the Natural History Museum's latest exercise, been taken as a classic example of the gradual evolution of a single gene pool. Certainly there is not any serious doubt about *Homo erectus* being directly ancestral to *Homo sapiens*.

Yet the concept of one species being directly ancestral to another is contrary to the rules of cladistics. So we read in the section on *Homo erectus* (under the heading "Not our direct ancestors"), that "The *Homo erectus* people were not quite like us. . . the *Homo erectus* skull has several characteristics that the modern skull does not share. Because of these special characteristics, we think that the *Homo erectus* people were not our direct ancestors".

But then on the opposite page is a photograph of the Petralona skull, from Greece, which the author considers an example of *Homo sapiens* or *Homo erectus* because of its mixture of features. This particular skull makes nonsense of the entire methodology being promoted in the books and exhibition. According to the stated assumptions of cladistics none of the fossil species can be ancestral by definition. This presents the public for the first time with the notion that there are no actual fossils directly antecedent to man. What the creationists have insisted on

for years is now being openly advertised by the Natural History Museum.

The scientists on the museum staff, be they experts on dinosaurs or on fossil man, have had their scientific judgement over-ridden by the Department of Public Services. What exactly is the cladistic framework to which the Public Services Department is so fervently dedicated? Why is there such a fanatical insistence that data should be presented within such a framework?

And why should there be a deliberate policy that involves the removal from the public gaze of important and scholarly exhibits in the museum such as the Insect Gallery and the Fossil Mammal Gallery? Is it because they provide too dramatic a contrast with the propaganda of the new-style exhibits?

The questions that should arise in everyone's mind are: what is this all about, what actually is going on and what is behind it all? The answers can be found by reading the literature of cladistics. The tenor of this is seen in its abuse of E. Mayr and G.G. Simpson, and indeed of Charles Darwin himself, because of their firm adherence to the concept of gradualism and to the idea that the processes that can be observed at the present day, when extrapolated into the past, are sufficient to explain changes observed in the fossil record. The synthesis of population genetics and palaeontology presented by Simpson in his two seminal works *Tempo and mode in evolution* (1944) and *The major features of evolution* (1953) is anathema to cladists.

The next question is why should the notion of gradualism arouse passions of such intensity? The answer to this is to be found in the political arena. There are basically two contrasting views with regard to human society and the process of change through time: one is the gradualist, reformist and the other is the revolutionary approach. The key tenet of dialectical materialism, the world outlook of the Marxist-Leninist party according to J.V. Stalin, is in the recognition of "a development in which the qualitative changes occur not gradually but rapidly and abruptly, taking the form of a leap from one state to another" (Engels). This is the recipe for revolution. If this is the observed rule in the history of life, when translated into human history and political action it would serve as the scientific justification for accentuating the inherent contradictions in society, so that the situation can be hurried towards its appropriate "nodal point" and a qualitative leap supervenes.

With regard to evolution and the fossil record, neither Engels nor Lenin, both of whom discussed the subject at length — to their great credit — insisted upon a pattern of such qualitative leaps, they were merely content to see in evolution and the fossil record evidence of change, albeit gradual.

This has always been a matter of some disquiet for Marxist theorists. If it could be established that the pattern of evolution was a saltatory one after all, then at long last the Marxists would indeed be able to claim that the theoretical basis of their approach was supported by scientific evidence. Just as there are "scientific" creationists seeking to falsify the concept of gradual change through time in favour of catastrophism, so too there are the Marxists who for different motives are equally

concerned to discredit gradualism.

What is going on at the Natural History Museum needs to be seen in this overall context. If the cladistic approach becomes established as the received wisdom, then a fundamentally Marxist view of the history of life will have been incorporated into a key element of the educational system of this country. Marxism will be able to call upon the scientific laws of history in its support, with a confidence that it has previously enjoyed.

This is the course of action to which the authorities of the Natural History Museum seem to have committed themselves either unwittingly or willingly.

University of Reading, UK.

## Refrigerator brew

SIR — One of the problems associated with Legionnaires' disease lies in the tracking down of the source of infection. Air conditioning systems seem to be prime suspects. So far as I am aware, nobody has thought of looking behind refrigerators. Having had occasion to do this recently, I was taken aback to discover that a self-defrosting refrigerator may provide the ideal breeding ground for a wide range of microorganisms.

At the back of a self-defrosting refrigerator there is a reservoir to collect the water as it is discharged. This water remains stagnant, gradually evaporating until it is replenished by the next automatic defrosting. With some designs the cooling coil passes through this reservoir to hasten evaporation. The result is a warm broth ideally suited to the proliferation of microorganisms. After a year or two stood around in a hospital environment such reservoirs might well harbour some very interesting cultures indeed. Even the ordinary household must pick up some pretty virulent infectious agents from time to time.

I have now taken the precaution of adding a dash of disinfectant to the brew. Hospital authorities might care to adopt the same simple measure.

ROBERT T. GREEN

15 Clifton Gardens,  
London NW11, UK

## Frequency tripling

SIR — Your correspondent's comments on the US inertial-confinement fusion (ICF) programme contains a minor inaccuracy (*Nature* 16 October p.573). University of Rochester scientists have, in fact, frequency-tripled the output of their glass laser thus converting the 1.054  $\mu\text{m}$  light to 0.3513  $\mu\text{m}$  radiation at high efficiency. Experiments using frequency-doubled light, at 0.53  $\mu\text{m}$  have been done or are underway at many laboratories, notably the Science Research Council Rutherford Laboratory, the Centre d'Etudes de Limeil (France), GRECO-Interaction Laser Matiere, Ecole Polytechnique (Palaiseau, France), KMS Fusion Inc., and the Lawrence Livermore National Laboratory. The Ecole Polytechnique group recently has reported on experiments using 0.26  $\mu\text{m}$  radiation, the 4th harmonic of 1.06  $\mu\text{m}$  light.

La Jolla Institute,  
La Jolla, California

PETER HAMMERLING

## NEWS AND VIEWS

## What prospects for an X-ray laser?

WHAT are the chances that one day there will be machines capable of producing short but intense pulses of virtually monochromatic X rays, for all the world like lasers that function at the short-wavelength end of the spectrum? And if such machines can be built, what purposes will they serve? The notion that a machine with such a specification might be the basis of yet another military weapon will no doubt quickly capture the imagination of newspaper-headline writers. In reality, of course, the Earth's atmosphere is as opaque, more or less gram for gram, as are other materials. For those who brood about "death rays" for the benefit of science fiction literature, what matters (or should matter) is not the wavelength of the radiation but the amount of energy that can be delivered by a radiation beam and the efficiency with which it is absorbed by the target. Reflection will also show that the present attempts to develop X-ray lasers, centred as they are on machines that differ very little from high-energy particle accelerators, suggest that X-ray lasers — if they can be built — will hardly be the kinds of portable devices of which generals and their staffs are fond. In other roles, however, and especially in strictly scientific applications, devices of this kind, however cumbersome, would be of great benefit. So what are the chances that they will eventually be constructed?

This question has obviously perplexed those within the European Science Foundation who have been concerned with the project to plan a European facility for synchrotron radiation. At the general assembly of the foundation last week in Strasbourg, those responsible for this project, which is essentially a scheme for building an electron storage ring operating at 3 GeV and designed to produce copious amounts of synchrotron radiation, let it be known that they are undeterred by the chance that an X-ray laser may eventually make their own project unnecessary. In this phlegmatic view, the planning group is surely on safe ground. The chances that it will be possible to construct machines operating as lasers in the X-ray range within the lifetime of the proposed European synchrotron machine are small. Further ahead, however, there is a reasonable chance that something may be possible.

The starting point for this speculation is the wave of excitement generated in the past few years by the concept of the "free-electron laser", an innovation largely due to Dr J. Madey at Stanford University in 1976 (Elias, L.R. *et al. Phys. Rev. Lett.* **36**, 717; 1976). The working principle of these devices is a curious amalgam of old-fashioned 1940s technology and the more recent sophistication of the particle-beam technologists (see J.N. Elgin *Nature News and Views*, 1 May 1980, and references therein). Suppose a beam of electrons travelling along a tube is subjected to a sequence of transverse magnetic fields, alternately in one direction and the opposite. At each step, the electrons (accelerated as they will be along the third cartesian axis) will radiate electromagnetic energy. As Maxwell's equations have it, a beam of electrons processed in this way should be a source of a radiation beam directed along the axis of the system. Moreover, the wavelength of the radiation should be determined to a first approximation only by the energy of the electrons and the geometrical periodicity of the magnetic field. The more frequent the alternation of the direction of the magnetic field along the axis of the beam, the shorter the wavelength of the radiation, which is (or should be) related inversely to the square of the energy of the electrons. The planning of the proposed European synchrotron radiation facility is based almost entirely on the notion that a circulating beam of stored electrons should be subjected to a sequence of such corrugated magnetic fields, called "wigglers" in the trade.

The novel development at Stanford University was the recognition that a beam of electrons travelling through a corrugated magnetic field should also behave as if it were the working material of a laser. In other words, if an electron beam traversing a wiggling magnetic field is also exposed to radiation of the frequency characteristic of the geometry and the electron energy, radiation at that same frequency will be stimulated and, if there is a pair of mirrors somewhere, energy from the mechanical motion of the electrons will be converted into a beam of radiation of wavelength determined in advance only by geometry and electronic energy (with the actual strength of the magnetic field as a second approximation correction). So, would-be designers of X-ray lasers will say, why not go the whole hog, pushing the electron energy as high as possible but reducing the geometrical wavelength of the alternation of the wiggling magnetic fields until the predicted wavelength is in the X-ray region?

There seems little doubt that lasers working on this principle will be designed and built in the years ahead. For the time being, however, the wavelengths at which free-electron lasers are being designed or played with are modestly long. The first experiments at Stanford University demonstrated laser action at 10.6  $\mu\text{m}$ , well into the infrared. Although there are more conventional types of lasers which function in this region of the spectrum, the prospect that the wavelength of radiation from a free-electron laser may be adjusted simply by changing the energy of the electron beam suggests that devices built on such a principle should be more 'tuneable' than more conventional infrared lasers. The immediate prize in the sights of those now developing this new technology is, however, that of being able to construct lasers that operate in the ultraviolet. The potential benefits of such devices are self-evident. For the first time, it would, for example, be possible to make precise studies of several photochemical processes at present inaccessible to observation. The snags are unfortunately also clear. Free-electron lasers are likely to be less efficient at increasing energies (although much depends on the geometry) while technical problems of arranging for a geometrically rapid corrugation of a magnetic field entail the complications of handling superconducting magnets. This part of the game, nevertheless, may be well worth the candle because of the potential usefulness of ultraviolet lasers in the separation of uranium isotopes or the stimulation of thermonuclear fusion.

The potential of free-electron lasers seems to have been clearly recognized in the United States, where much technical development is under way. The best known plan is that of the Brookhaven National Laboratory on Long Island, where a 700-MeV storage ring will be commissioned next year with the intention of producing laser radiation in the optical and near-ultraviolet in 1982. Most other projects, in which industrial companies such as TRW Incorporated and Bell Telephone Laboratories have taken an interest, appear to be aimed at exploring still inaccessible parts of the infrared spectrum. Given the present limitations of even superconducting magnet design, it is inevitable that people should be forced to use beams of electrons with energies approaching 1 or more GeV. But these, of course, are early days. With any luck, free-electron lasers should be operating in the ultraviolet within the next few years. There after, it should be relatively easy to decide how the technology might be pushed still further. By the end of the decade, soft X-ray laser sources, however inefficient, should be in operation. The hard X-ray source that will make possible direct measurement of atomic and molecular energy levels will be further ahead, but not out of reach.

# Gene regulation: new, old and remote controls

from Adrian Minty and Peter Newmark

A few months ago in these columns, due warning was given that the 5' ends of every gene under the sun were "in for a beating with mutagens and nucleases in the quest for the eukaryotic promoter" (*Nature* 285, 356; 1980). Two European meetings\* with many presentations in common have since demonstrated the validity of that prediction, whilst illustrating that introns and regions far removed from the 5' ends of genes (see Fig. 1) are also coming under close scrutiny as possible sites of gene regulation.

## The Hogness/Goldberg/TATA box

It has been recognized for some time that most of the eukaryotic genes which are transcribed by RNA polymerase II have a very similar, short nucleotide sequence about 30 nucleotides upstream from the place where transcription begins. The sequence is invariably AT rich and is most commonly known as the TATA (tar-tar) box but at other times as the Hogness box, since it was first recognized in the Stanford laboratory of D. Hogness. Purists, however, note that the only formal citation for the discovery at present is to the 1979 Stanford University thesis of M. Goldberg and hence refer to the Goldberg-Hogness box.

Is the TATA box essential for the initiation of transcription? An answer of sorts is emerging from a comparison of the *in vitro* and *in vivo* transcription of intact, cloned genes with cloned genes that have mutated, deleted and/or replaced TATA boxes.

For *in vitro* transcription there is, at first sight, a good deal of evidence that the TATA box is essential. Most strikingly, mutation of the chicken conalbumin gene box from TATA to TAGA reduces

transcription by more than 95 per cent (P. Chambon *s*, Strasbourg). In cruder tests, the elimination of TATA box regions of the chicken ovalbumin gene (M. J. Tsai *a*, Houston), the  $\beta$  globin gene (R. Flavell *a*, National Institute for Medical Research, London) or the adenovirus late region (P. Sharp *s*, MIT) reduced or halted the initiation of transcription.

Unfortunately, matters are more complicated than that. For example, several viral genes do not have TATA boxes. Furthermore, both R. Kamen (*s*, ICRF), working with the polyoma virus early region, and P. Chambon, working with the SV40 early region, reported that deletion of the TATA box regions did not prevent transcription but did shift the position(s) at which it started. From TATA box deletions and a series of other deletions, Chambon is of the view that the efficiency of transcription is controlled both by the TATA box and by regions lying downstream from it, close to the site of initiation of transcription, while the TATA box alone is responsible for fixing the site of initiation. Not everyone's data seem to fit even that fairly unspecific view and that is the way matters are likely to stay until a good deal of progress has been made in defining the ideal conditions for *in vitro* transcription.

Meanwhile, a complementary approach is to look at *in vivo* transcription. Here there is general agreement that deletion of the TATA box affects the site far more than the efficiency of initiation. This is so for the SV40 early region in monkey cells (Chambon *s*), sea urchin H2A histone genes in *Xenopus* oocytes (M. Birnstein *a*, Zurich), yeast iso1-cytochrome *c* genes in yeast (G. Faye *s*, Seattle and Orsay) and mouse  $\beta$  globin genes in monkey cells (D. Hamer *s*, NIH).

## Upstream controlling region

Much the most interesting and broadly consistent result to come, in recent months,

from a spectrum of *in vivo* studies, is that there are regions further upstream than the TATA box which can modulate RNA polymerase II-dependent transcription. What is more, whereas deletion of these upstream controlling regions can drastically reduce *in vivo* transcription, it can be without effect on *in vitro* systems.

For example, P. Dierks (Institute of Molecular Biology, Zurich) reported that deletion of the CAAT box, found 80 nucleotides upstream from the cap site of a number of globin genes, markedly reduced their transcription in mouse L-cells, although he agreed with Flavell that this deletion was ineffective *in vitro*. In the case of the SV40 early region, Chambon reported that the crucial upstream region lay within a GC-rich region of a 72-base pair repeated sequence that, at its closest, is some 100 base pairs upstream from the TATA box.

Another interesting example is the histone H2A gene (C. Hentschels, Zurich). Deletion of a segment of DNA positioned from 184 to about 520 base pairs upstream of the initiation site reduced transcription by 15–20-fold. Mysteriously, the inversion of this region, which is characterized by its AT-richness and some largish palindromes, led to a fivefold increase in transcription.

As a final example of remote control of gene activity, there are the wild-type strains of *Drosophila* which do not show the normal 'puffing' of band 3C11-12 on the X chromosome in response to ecdysone. D. Hogness (*s*, Stanford) reported that the relevant gene in each of four such strains had a 50–150-base pair deletion approximately 200 base pairs upstream from the 5' end.

How does the remote control of transcription work? There are at least three possibilities. The first is that the upstream region binds a protein which affects transcription. The second is that it binds

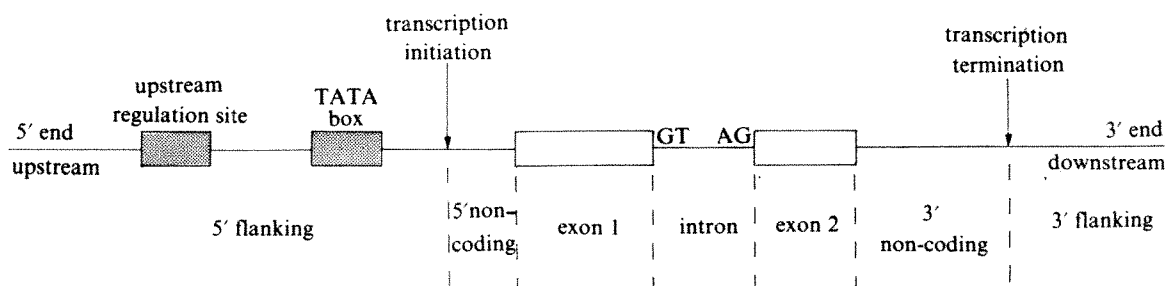

Fig. 1 Consensus polymerase II gene structure. Not to scale.

\*Fourth Arolla Workshop, Arolla, Switzerland, 18–22 August 1980 and INSERM conference on 'Structure and Expression of Eukaryotic Genomes', Domaine de Seillac, 21–25 September 1980. Speakers at the former are identified by an *a* before their affiliation and those at the latter by an *s*.

RNA polymerase II, secondary structure being invoked to explain how the enzyme also binds to sites near to the point of initiation. And the third, and most fashionable, explanation is that the upstream sites phase (determine the spacing of) the nucleosomes in relation to the DNA sequence, the phasing determining whether or not a downstream gene is transcribed.

That chromatin structure plays a part is suggested by the hypersensitivity to DNase I of the 5' ends of the heat-shock genes (S. Elgin *a*, Harvard; see also Wu, C. *Nature* **285**, 854; 1980) and histone genes (A. Worcel *a*, Princeton) of *Drosophila*. Results that fit that trend are also beginning to emerge from a study of the DNase I hypersensitivity of SV40 in infective or integrated form (C. Cremisi *s*, Fred Hutchinson Cancer Center, Seattle). Furthermore, electron microscopy shows there to be a break in the regular dispersal of nucleosomes around the SV40 minichromosome close to the presumed promoter site (Y. Aloni *a*, Weizmann Institute and *Nature* **285**, 263; 1980; M. Yaniv *s*, Pasteur Institute and *Cell* **20**, 65; 1980). Polyoma virus, which has a similar nucleosome-free region, does not normally grow on undifferentiated teratocarcinoma cells. Yaniv, however, described a mutant which could grow on those cells and which had an altered DNA sequence in the presumed promoter region and a displaced nucleosome-free region, reinforcing the view that there is a relationship between the sequence of DNA, its organization into nucleosomes and the control of transcription.

#### Introns

As more introns are sequenced, new features of interest emerge. These include the recognition of repetitive sequences within the introns of the ovalbumin-related 'X' gene (J.-P. Mandel *s*, Strasbourg) and the vitellogenin gene (G. Ryffel *a*, University of Bern).

It is customary to believe that introns are spliced out whole, from the GT at the 5' end to the AG at the 3' end (the junction or boundary sequences). But E. Avvedimento (*s*, NIH; see *Cell* **21**, 689; 1980) has identified three possible internal splice sites in an intron of the chick  $\alpha$ 2-collagen (type 1) gene. He proposed that a first step in the removal of this intron could be the splicing of the 3' end to any one of the three internal sites and backed up that proposal with evidence of the presence of the predicted RNA species in the nucleus of chick fibroblasts. A two-step splicing out of one of the introns of a mouse  $\alpha$ -amylase gene is similarly indicated (O. Hagenbuehle and U. Schibler *a* and *s*, ISREC, Lausanne).

A more interesting feature of the  $\alpha$ -amylase system is that it may provide the first example in eukaryotes higher than viruses of the production of mRNAs with alternative 5' ends from the same DNA sequence. That at least is the explanation favoured by the Lausanne group for the

fact that the major species of  $\alpha$ -amylase mRNA in the mouse liver is identical to that in the salivary gland except that its 5' non-coding sequence is extended by about 100 nucleotides. Analysis of genomic clones from the two tissues supports the view that the alternative mRNAs are derived by tissue-specific transcription and splicing of an identical DNA sequence. Why and how this happens is uncertain.

It has been postulated that splicing is initiated by the base-pairing of one of the small nuclear (Sn) RNAs, called U1, to the intron-exon boundary sequences in gene transcripts. M. Jacob (*a*, Strasbourg) presented a list of 60 intron-exon boundary sequences in eukaryotic pre-mRNAs and concluded that, in the majority of cases, the homology between these and U1 was probably not, in itself, sufficient to ensure a stable hybrid. Approximately 40 per cent of SnRNAs in the cell are associated with heterogeneous nuclear RNA at a ratio of 1 or 2 molecules of SnRNA per 2,500 nucleotides, indicating that they are not structural components of heterogeneous nuclear ribonucleoproteins (Jacob). T. Pederson (*a*, Worcester Foundation) reported from cross-linking studies *in vivo*, that U1 is actually bound to heterogeneous nuclear RNA in the cell. This appears not to be the case for another 'processing RNA' candidate, the adenovirus VA RNA, which is not found in adenovirus nuclear ribonucleoproteins (Jacob *a*; J.M. Blanchard, Montpellier).

A different mediator of splicing was proposed by P. Slonimski (*a,s*, Gif) for the transcript of the yeast mitochondrial gene for cytochrome *b*. He proposes that certain introns are spliced out with the help of proteins ('maturases') encoded in the introns themselves.

Several facts favour that interpretation. They include the recent discovery that the second intron of the cytochrome *b* gene contains an open reading frame of considerable length while mutants containing stop codons within that intron accumulate unspliced transcripts of the gene, a defect that can be corrected by *in vivo* complementation. Furthermore,

those mutants contain proteins of the right size to be the 'maturase' truncated in accordance with the position of the stop codon. Neat though this system is, particularly in terms of autoregulation, there is very little evidence for its generality.

#### Post-transcriptional regulation

That gene expression can be regulated after, as well as at, transcription was made clear by several contributors. M. Rosbash (*a*, Rosenstiel Center, Waltham) described a temperature-sensitive mutant of yeast (RNA 2) in which the synthesis of ribosomal protein is inhibited despite normal transcription of the ribosomal protein gene. Since the unspliced transcript accumulates in the nucleus, it seems probable that the primary defect lies in the processing of the transcript to mRNA. A similar situation exists for globin mRNA in erythroblasts transformed by avian erythroblastosis virus (A. Therwath *a*, IRBM). J. Nevins (*a*, Rockefeller, New York) showed evidence that a part of the adenovirus genome expressed late in infection is also efficiently transcribed early in infection but that few cytoplasmic mRNA molecules are formed from the transcripts; again this reflects a defect in processing since polyadenylated precursor molecules accumulate in the nucleus. However, the effects of inhibitors of protein synthesis on adenovirus expression led L. Phillipson (*a*, University of Uppsala) to propose that a viral gene product encoded in the early region controls, either directly or indirectly, translation of early adenovirus mRNA *in vivo*.

Finally, Hereford (*a*, Rosenstiel Center) reported that duplicating the yeast histone genes by genetic manipulation resulted in a doubling of transcription whilst the overall level of histone mRNA remained constant due to a halving of the mRNA half-life. Further elucidation, at a molecular level, of the control of eukaryotic mRNA production remains a major task for the 1980s. □

## Deep drilling in African lakes

*from N.J. Shackleton*

THE climatic environmental history of Africa is a major unknown on a time scale from thousands to millions of years. So far as the Pleistocene is concerned, we are building up a fairly complete picture of the characteristics of climatic change, both on the northern continents and over the oceans. Moreover, we have sufficient information to relate reliably the time sequences from the oceans with those of

glaciated areas. To a first approximation, climate changed more or less synchronously in North America, Europe and over much of the sea surface; however, the picture of climatic change in Africa has been surprisingly different.

In the past, the dry areas of Africa have experienced episodes of much greater wetness, which gave rise to increased lake areas, bigger rivers and more extensive

vegetation. At first it was assumed that these 'pluvial episodes' occurred at times of glaciation in the north. However, the most recent 'pluvial' is reliably dated over large areas of Africa to about between 12,000 and 5,000 years ago. Unfortunately, our records from Africa are too young to allow investigation of the previous occurrence of similar pluvial episodes. Thus we cannot usefully integrate the history of tropical rainfall with older records of other climatic variables. Indeed, we have no idea of the frequency of pluvials during the Pleistocene.

Between 21 and 27 August, an international working group, convened by Dr Dan Livingstone (Duke University, North Carolina) and Dr Neil Opdyke (Lamont Doherty Geological Observatory), met at the offices of the National Science Foundation (NSF) in Washington to plan a major drilling project to tackle this and related problems. Funds for the meeting came from the Anthropology Division of the NSF, but the disciplines represented were numerous, including palynology, magnetostratigraphy, organic and inorganic geochemistry, and the study of diatoms, stable isotopes and evolutionary biology as well as African prehistory. As well as conventional dry-land drilling expertise, we had a representative of the

Deep-Sea Drilling Project whose presence was appreciated partly because of the potential value of their drilling experience (especially with the new Hydraulic Piston Corer) and partly because of their unique experience in managing a major sediment-sampling programme for the benefit of a very large scientific community.

The NSF has already funded a seismic survey which will be conducted during the next year and which will hopefully cover three lakes. A great deal of the meeting was devoted to a discussion of the relative scientific and logistical merits of over a dozen tropical lakes in Africa (we resisted the temptation to spend much time on lakes which seem logistically impossible at present). The lake most suitable for a first sampling is Lake Bosumtwi in Ghana. This occupies a crater that is thought to have been formed by meteoric impact about a million years ago. Preliminary study of short cores covering the past 30,000 years or so shows that it preserves a good vegetational history and, so far as the million years recorded is concerned, is the most attractive of the lakes we discussed. Drilling of this lake should recover very valuable material for studying the early diagenesis of organic-rich sediments. The hypothetical origin of the Ivory Coast tectite-strewn field will be tested at source.

Most important, we will have a datable and continuous record of the climate of the past million years in the tropics where rain, rather than temperature, is the most important climatic variable. The extent to which this record can be explained in terms of current hypotheses will be an important test of our present understanding of the causes of climatic change.

With regard to the potential for a record spanning many million years, Lakes Malawi, Tanganyika and Turkana seem to offer the greatest number of advantages and should be covered in the seismic survey effort.

It was clear to the meeting delegates that the environmental history of any of the East African lakes must, over the long term, be intimately connected with its tectonic evolution, and conversely, that any deep drilling in one of these will arouse considerable interest from a wider section of the geological community. The consensus of the meeting was that a project to drill in the major African lakes, although expensive, will certainly be worthwhile in terms of the interest the results will hold for many different disciplines. □

## Herpes simplex virus in latent infection

*from Howard Marsden*

FOLLOWING initial infection of humans, herpes simplex virus (HSV) appears to be maintained in a latent state either for the lifetime of the individual<sup>1</sup> or in some individuals is periodically reactivated to produce overt lesions. Important questions arise, such as: in what tissue(s) is the virus latent, and what is the molecular basis of latency?

Goodpasture's suggestion<sup>2</sup> that HSV is latent in neuronal tissue has been substantiated in the mouse<sup>3</sup> where, after experimental infection in the footpad, two phases could be distinguished. First is an acute phase of one or two weeks during which virus can be recovered from cell-free homogenates of lumbrosacral ganglia. This is followed by a latent phase during which infectious virus is no longer detectable but in some animals virus can be recovered by co-cultivating explanted ganglia with sensitive cell monolayers on which the virus can form plaques. In this way, HSV-1 could be recovered not only from the peripheral but also, less frequently, from the central nervous system, though not from any non-neural tissue<sup>4</sup>. This observation suggested that in

the mouse, HSV latency is restricted to tissues of neural origin. However, Scriba subsequently demonstrated<sup>5</sup> that HSV-2 was recovered preferentially, and HSV-1 exclusively, from the footpad (the site of primary inoculation) of latently infected guinea pigs. More recently, Hill, Harbor and Blythe similarly recovered HSV-1 from the skin of latently infected mice<sup>6</sup>, although earlier attempts by other investigators had been unsuccessful. Are these really conflicting observations or do they reflect differences in the efficiency with which virus can be detected?

Latency involves three separate but related processes — not only establishment and maintenance but also reactivation. The virus assay method by nucleic acid hybridization used by Cabrera *et al.* (*Nature* this issue, p.288) does not necessitate formation of infectious virus particles and thus allows discrimination between the establishment and maintenance steps and the reactivation step. During the acute stage following corneal inoculation of HSV, infectious virus could be detected both in brain tissue (90 per cent of mice positive) and

trigeminal ganglia (100 per cent of mice positive); 8 weeks after inoculation, during the latent phase, virus could be reactivated by explantation and co-cultivation from 95 per cent of the trigeminal ganglia but from only 5 per cent of the brain tissue explants — yet by DNA reassociation techniques, HSV DNA sequences were detected in 30 per cent of brains of mice harbouring latent HSV in their trigeminal ganglia. The authors conclude that virus is not eliminated from the brain tissue but is maintained in a state which cannot be reactivated by the explantation techniques used.

What is this state and are all sequences of the HSV genome present? Inability to reactivate in the absence of complete genomic sequences would hardly be surprising. However, the presence and expression of an incomplete genome could have considerable consequences for the organism. Perhaps nucleic acid hybridization studies using cloned fragments of the genome will provide some insight.

Another approach to detect HSV genetic material in explant organ cultures is to superinfect explanted human ganglion

tissue with temperature-sensitive (*ts*) mutants of HSV-1 (ref. 7). Using this method, Brown *et al.* recovered wild-type virus from explant cultures which had been negative by co-cultivation for 45 days, and inferred that the *ts* mutant must have been complemented or rescued by genetic information in the ganglia. The authors suggest use of restriction enzymes to try to detect in the putative rescued virus DNA sequences which are not present in the *ts* mutant.

An important question is whether any of the viral genome is expressed during the latent state. Puga *et al.*<sup>8</sup> could find no HSV mRNA using reassociation techniques capable of detecting one genome equivalent of mRNA in 2,000 cells. On the other hand, using *in situ* hybridization, Galloway *et al.*<sup>9</sup> reported HSV mRNA in 0.4–8 per cent of human ganglia. HSV-specific thymidine kinase (TK) activity was observed in the sensory ganglia of mice up to 60 days after infection<sup>10</sup> but not in the skin or ganglia of quinea pigs, even with an assay which could detect the activity of one lytically infected cell in 3,000 uninfected cells<sup>11</sup>. We do not yet know whether any of the observed expressions are necessary for maintenance of the latent state or whether they reflect the spontaneous reactivation of cells which may subsequently be eliminated from the animal.

A different approach with potential for recognition of the viral functions necessary for latency is the use of HSV mutants. Tenser and colleagues<sup>12,13</sup> found that TK-negative mutants of HSV established latent infections in the trigeminal ganglia of both guinea pigs and mice with a lower frequency than that of TK-positive virus, suggesting that expression of this enzyme is necessary for latency. A collaborative study between Stevens' group (University of California, Los Angeles) and Subak-Sharpe's (Glasgow, UK) identified six temperature-sensitive mutants of HSV-1 which produce latent infections in mice with reduced frequency. One of these mutants (*tsK*) has a lesion in the immediate-early polypeptide  $V_{mw}$  175 (ref. 14) and appears to be blocked at or near the immediate-early stage of infection. The combined results of Preston<sup>14</sup> and those of the mutant latency study suggest that expression of at least one immediate-early function and one or more later virus functions is necessary for latency<sup>15</sup>.

The techniques hitherto employed in the isolation of *ts* mutants generate mutations in genes essential for growth in tissue culture. Genetic manipulation techniques will also allow isolation of mutants lacking sequences not essential for growth in tissue culture but which might be essential for latency. Screening of such deletion mutants for latency should be informative. □

## New directions in spectroscopy

from Derek Stacey

ATOMIC SPECTROSCOPY has a long and distinguished tradition. Its history is closely linked with that of quantum mechanics; atomic structure and the interaction of atoms with radiation provided both the inspiration and the testing ground for many of the theoretical advances which took place in the first half of this century, from the early quantum theory of Bohr to quantum electrodynamics (QED). Now that the emphasis has been passed on to elementary-particle physics, what remains to be done in atomic spectroscopy? A recent conference\* showed how spectroscopists have responded to this challenge.

First, there are some areas in which fundamental questions can still be studied. One paper, given by a team from CERN and the University of Pisa, described progress in an experiment to measure the birefringence of empty space (E. Iacopini and E. Zavattini *Phys. Lett.* **85B**, 151; 1979). According to QED, ordinary plane-polarized light becomes slightly elliptically polarized when travelling through an evacuated region in which a magnetic field exists. As there is nothing else present, it follows that the photon-photon interaction itself is responsible for the birefringence. Measurement of the induced ellipticity would give a direct test of this interaction at very low energies; this would be interesting because the birefringence is a genuine vacuum-polarization effect, arising only as a result of virtual pair creation. Apart from the interest in testing QED, the effect could have implications for astrophysics when one is dealing with the propagation of light through regions which may be subject to strong magnetic fields.

The problem with the experiment is the smallness of the effect. The idea is to shine a linearly polarized beam from an argon-ion laser into an evacuated region where there is a magnetic field of 8 teslas, provided by superconducting magnets; the effect is proportional to the fourth power of the field, so it is important to make this as large as possible. A mirror system causes the beam to cross this region many times, so that the effective path length through

the field is several kilometres. Even so, the ellipticity predicted for the emerging beam is only around  $10^{-12}$ . The measurement is carried out using familiar methods of analysing polarized light, the object being to detect changes which occur synchronously with the switching of the magnetic field.

The project brings to mind the experiments which use rather similar optical techniques to measure the rotation of the plane of polarization of light when it passes through an atomic vapour; the rotation gives a measure of parity non-conserving effects in the atomic system and hence demonstrates the presence of weak, neutral currents in atoms. These experiments are of fundamental interest and considerable effort has been put into them, but they have still taken several years to measure effects at the  $10^{-7}$  level. Thus the prospects for the new test of QED seem discouraging at first sight, but this could be a misleading comparison. Much of the difficulty of the parity experiments arises because one has to search for an effect which is sensitively dependent on wavelength. This problem does not arise in the QED test, in which the switching of the magnetic field provides the only necessary discriminating factor. Nevertheless, success in this experiment would be a major technical achievement.

Although comparatively few groups are working on such fundamental problems, the contributed papers showed that the field of atomic spectroscopy, far from declining, is showing a remarkable resurgence. This is largely due to the profound influence that the tuneable dye laser has had on atomic physics. During its early days, powerful spectroscopic techniques based on the device were developed but were usually applied to systems already well understood. Only now is the full potential of dye-laser methods becoming apparent; they have transformed established fields of study and opened entirely new areas for investigation — Rydberg states, collisional redistribution of radiation, super-radiance and so on. The attraction of this type of work is easy to see; in many branches of physics, anyone wishing to take advantage of advances in technology must join a team working at a major central faculty. The tuneable laser is a comparatively cheap

\*Annual conference of the European Group for Atomic Spectroscopy, held in Pisa, 2–5 September 1980.

device which permits a whole range of new experiments to be carried out in an ordinary laboratory.

Several papers described improvements in dye-laser techniques, but the most significant development in this area has been the emergence of the new generation of dye lasers based on the ring geometry. Ring lasers are inherently much more powerful and stable than the earlier standing-wave devices, and one reason for their importance is that they allow tuneable-laser methods to be applied in the ultra-violet. Most atoms have hitherto been inaccessible to the simpler dye-laser techniques because the tuning range of available dyes does not extend to short enough wavelengths. A ring laser operates with the same dyes but gives sufficient power to allow frequency doubling, or frequency generation, by mixing with the output of fixed-frequency lasers.

Another reason for the present interest in atomic spectroscopy is that the various techniques developed over the years primarily as spectroscopic tools are finding wider application. An invited paper presented at the conference by F. Laloë (Saclay Nuclear Research Centre, Paris) dealt with the properties of polarized  $^3\text{He}$  (that is, nuclear spins all parallel) (C. Lhuillier and F. Laloë *J. Phys.* **40**, 239;

1979). The connection with atomic spectroscopy is that the most promising of the methods proposed to prepare a sample of this material is based on the standard spectroscopic technique of optical pumping. (In particular, a newly explored colour centre in NaF seems well suited for pumping the  $2^3\text{--}2^3\text{P}$  transition, an important step in the preparation process [L.F. Mollenauer *Opt. Lett.* **5**, 188; 1980].) The talk reviewed the remarkable properties predicted for this fluid; they derive from the indistinguishability of the particles and can give rise to 'quantum effects' even when the system is in the form of a low-density gas. This is because the transport properties depend on the collision cross-section, and the Pauli Principle prevents the atoms from hitting each other. Other intriguing predictions include changes in the liquid-vapour and liquid-solid equilibrium pressures (C. Lhuillier and F. Laloë, *op. cit.*). It may be some time before any of these effects are demonstrated practically. However, the project is a good example of the way in which atomic spectroscopy continues to influence the development of other areas of physics. □

Derek Stacey is at the Clarendon Laboratory, University of Oxford, UK.

the rock record for minerals or chemical constituents that require oxygen for their formation. Unfortunately, although they exist, the time of their formation in the geological record fails to provide unequivocal evidence for an oxygenic atmosphere, and one major point to come out of the conference was that no single piece of evidence, in itself, would be sufficient to establish the existence of an oxic atmosphere. Rather, a whole sequence of analyses must be done on the same rocks in order for valid interpretations to be possible. Analyses have so far been too fragmentary to provide firm conclusions, although the weight of opinion, based primarily on the microfossil record and on iron and uranium mineralogy, is that oxygen probably first arose in significant quantities around 2 to 2.6 billion years BP. However, the interpretation of microfossil evidence is fraught with difficulty, as there are no microbial structures that can be unequivocally associated with oxygen evolution.

One of the four groups evaluated the evidence concerning Precambrian banded-iron formation. These formations are extremely important because they provide over 90 per cent of the minable iron deposits of the world. There was a major period in Earth history between 2 and 2.6 billion years BP when iron was precipitated in vast amounts, and after this time only very small deposits of this type of iron have deposited. The main Precambrian iron formation is rich in silica (chert) and has extensive characteristic banding (macro-, meso- and micro-bands), thus prompting the name banded-iron formations (BIF). These deposits probably formed as a result of sedimentation of oxidized iron on to ocean shelves, and because of the known chemistry of iron, it is clear that the Precambrian oceans could only have held in solution the vast amounts of iron necessary for BIF if the ocean waters were much less oxygenated than they are today.

The favoured model involves a circulating Precambrian ocean with an upper oxygenated layer and a lower anaerobic zone, the latter of which held a vast amount of ferrous iron. Movement of reduced iron into the surface waters, perhaps as a result of oceanic upwelling (analogous to the movements which bring up deep, cold, nutrient-rich waters on to shallow shelves in the present oceans), brought soluble iron to surface waters from where it was probably carried into closed basins for precipitation and sedimentation. The upwelling analogy involving marginal basins is strengthened by the facts that iron formations are enriched in phosphorus,

## Precambrian evolution

from Thomas D. Brock

THE PRECAMBRIAN constitutes the longest but least understood period of Earth history. In terms of biology, it is the period during which life arose and underwent extensive biochemical diversification. In terms of geology, it is when the continents and oceans became segregated and defined. Although today life plays a crucial role in geochemical processes at the surface of the Earth, geochemical events during at least part of the early Precambrian probably occurred in the absence of biological catalysis.

A number of ancient sedimentary deposits, some with important ore-bearing rocks, are accessible for study and analysis, the oldest of which is the Isua Supracrustal Group in Greenland (around  $3.8 \times 10^9$  years before the present [BP]). The only real clues to evolutionary processes in the Precambrian are found in the chemical and biological constituents present in these ancient rocks, and the aim of students of the Precambrian is to try to make sense out of the fragmentary records available. Although this is interdisciplinary research at its highest level, chemists, geologists and biologists rarely have the opportunity of meeting and working with one another. It was therefore particularly appropriate that a conference\* on Precambrian evolution was arranged that involved both geochemists and bioscientists.

Four separate topics were considered, each by a separate group containing chemists, geologists and biologists: (1) banded-iron formations; (2) stratified sulphide deposits; (3) organic geochemistry and palaeomicrobiology of ancient sediments; and (4) biogeochemical evolution of the ocean/atmosphere system. Although these topics were considered by separate groups, they so greatly overlapped that it was necessary for individuals to move from one group to another from time to time, a process encouraged by the format of the Dahlem Conferences.

Of over-riding importance for an understanding of Earth history is the estimation of the sequence of events leading to the formation of an oxygen-containing atmosphere. Oxygen arises today almost exclusively through plant photosynthesis, and the single most important feature in the evolution of higher-life forms was the appearance of this process. This must have occurred early in Earth history, but we do not know precisely when. Data from studies on chemical evolution suggest that life probably arose in an initially anoxic environment, and micropalaeontological evidence is strong that, by the Cambrian, the Earth's atmosphere contained nearly as much oxygen as it does today.

The geochemist looks carefully through

\*The Dahlem Conference on Mineral Deposits and the Evolution of the Biosphere, held during the first week of September 1980. A workshop report is also available: H.D. Holland and M. Schidlowski (eds) *Mineral Deposits and the Evolution of the Biosphere*, Dahlem Konferenzen (Verlag Chemie, Weinheim, FRG, in the press).

and by the purity of these deposits (absence of heavy metals). It is thought that the world-wide appearance of BIF between 2 and 2.6 billion years BP may be largely due to the development, for the first time, of wide continental shelves and enclosed basins adjacent to the deeper, oceanic areas. The cyclicity which led to banding was probably the result of seasonal climatic changes, perhaps controlling phytoplankton oxygen production.

During the discussion, it became clear that considerably more information is needed on iron oxidation states in Precambrian iron formations, as an indication of the oxidation states of the Precambrian oceanic waters. Since the presence of iron in Precambrian rocks provides some of the best evidence for the oxygen status of the atmosphere, it is essential that the oxidation state of iron during primary precipitation be established with certainty. Does the massive development of iron formation at 2 to 2.6 billion years BP represent the initial rise in oxygen in the atmosphere, or is it more related to the initial development of continental shelves, providing an appropriate habitat for iron deposition?

Stratified sulphide deposits display a host of features indicating that they formed at or near the sediment-water interface. Although it had been considered previously that some of these deposits were biogenic, the conclusion of the Dahlem workshop was that they had to have an external (possibly exhalative) source of metal and that the sulphur may represent a mixing of multiple sources (biogenic and hydrothermal).

An important biogeochemical tool, sulphur isotope fractionation, was carefully re-examined in the light of the evidence. Two components are needed for the formation of a sulphide deposit — a source of sulphide and a source of iron (to tie up the sulphide). Sulphide can come from either abiotic sources (hydrothermal or volcanogenic) or biotic sources (sulphate-reducing bacteria). Because bacterial sulphate reduction leads to the discrimination of  $^{34}\text{S}$  against  $^{32}\text{S}$ , it has been conventional to use isotope ratios of sulphur in sulphide deposits to infer biogenicity. However, more recent work on the isotope ratio distributions in sedimentary and hydrothermal deposits shows that a clear-cut conclusion on biogenicity is not possible. Most ancient sulphide deposits have a high iron content, and it was shown that such a high iron content is unlikely to develop in a typical modern sedimentary setting where biogenic sulphide is depositing. Modern analogues for the ancient stratified sulphide deposits are the Red Sea brine pools and the 'black smokers' at 21°N on the East Pacific Rise. If the Precambrian sulphide deposits are indeed largely abiotic, then it is impossible to determine

from an examination of these deposits the time of onset of biological sulphate reduction. It was concluded that extensive new data will be needed to elucidate the onset of this important step in biochemical evolution.

Many Precambrian deposits have extensive amounts of reduced carbon, analysis of which may provide clues to biological evolution. However, interpretation of such analyses requires careful application of concepts developed during studies on modern ecosystems. There is now available a wide variety of techniques that could be used in the study of Precambrian organic matter, including ion microprobe, pyrolysis-gas chromatography, high-resolution mass spectrometry (MS), photoacoustic spectroscopy, laser pyrolysis, high-pressure liquid chromatography (HPLC), HPLC-MS, high-resolution capillary gas chromatography,  $^{13}\text{C}$  nuclear magnetic resonance and X-ray diffraction. It is clear that a vast amount of information can be obtained, but it is vital that the analyses be carried out on carefully collected specimens, and that, as far as possible, combinations of methods be used, to permit cross-checking and a more precise interpretation.

Organic matter in ancient rocks can be divided into two major fractions, extractable organic matter (EOM) and kerogen (nonextractable). Because of the ease of analysis, EOM has been studied more extensively, but it is essential that the EOM studied be syngenetic with the rock and not a post-depositional replacement or contamination arising during processing.

The interpretation of the chemistry of both EOM and kerogen requires a knowledge of the organic chemistry of modern ecosystems and of how organic matter changes during diagenesis and catagenesis. Micropalaeontological studies are also vital as they provide clear evidence that life was involved in organic matter deposition or modification. Studies on carbon isotopes in ancient organic matter may provide evidence for biogenicity, provided the data can be interpreted properly in relation to modern processes (although the example for sulphur isotopes discussed above shows the dangers involved).

During the conference, it was frequently the case that biologists were turning to chemists for appropriate chemical evidence that would aid their studies, and that geologists were seeking biological evidence to confirm or expand their conclusions. One of the main conclusions of this conference was that no one science alone would provide an answer, and that progress can be made only when all proceed together. Much discussion during the conference centred on the problems of communication between biologists and geologists, and the need for more formal mechanisms of interchange. Although 'biogeochemistry' has been used as a term since the mid-1930s, it is only now emerging as a discipline in its own right. Another result of the Dahlem workshop was strong consideration for the formation of a new society to be called the 'BioGeo-Chemistry Society' that would bring together workers from a variety of fields for a concerted attack on some of the most fundamental problems of our times. □

## Green light in Heidelberg

*from a correspondent*

THE 200 or so molecular biologists who attended the sixth EMBO symposium\* in Heidelberg spent 3½ days discussing gene organization and expression in green plants. The surprisingly large size of the audience might suggest that the organizers had found a patch of fertile ground and that the topic was scientifically ripe. In the event, however, there turned out to be few converts to the green revolution. For the most part, the audience consisted of those already in the field, together with a sprinkling of volunteers from other disciplines and a few weeds from the recombinant DNA companies whose presence seemed to presage a new meaning for the term 'seed-money'.

### Nuclear genes

Much of the meeting was devoted to the presentation of the results of molecular cloning experiments. cDNA and genomic libraries of the genomes of several species of plants have been constructed and several genes, particularly those expressed at high levels, have been analysed in some detail. Most attention has been paid to the genes coding for the storage proteins of cereals and legumes, which are silent in vegetative tissues but extremely active at specific stages of seed development. For example, the set of genes coding for the ten or so superabundant proteins of soybeans is turned on immediately after flowering; the concentration of their mRNAs in the cotyledons increases steadily for the next 75 days, by which time 50 per cent of the total mRNA is composed of only these few species (Goldberg, University of California, Los Angeles). None or very

\*Thomas D Brock is at the University of Wisconsin.

\*'Molecular Biologists look at Green Plants', European Molecular Biology Laboratory, Heidelberg, 29 September — 2 October 1980.

little of this RNA is ever detected in axis or leaf cells.

DNA copies of seven superabundant mRNAs have been made and cloned in prokaryotic vectors. By hybridization selection, *in vitro* translation and immunoprecipitation, four of them have been shown to code for polypeptides of the 7 and 11S storage proteins as well as the Kunitz trypsin inhibitor. Although these proteins appear to be coordinately synthesized, their genes are not closely clustered. Hybridization experiments between cDNAs and representative clones from a genomic library show that the genes for superabundant mRNAs occur at most a few times within the soybean genome and do not map within 20 kilobases of one another.

A major problem, therefore, is that of how small, dispersed families of apparently unrelated genes such as these are controlled and simultaneously activated. Reassociation kinetic experiments rule out the possibility that the genes are differentially amplified during embryogenesis. Furthermore, no common feature has appeared from an analysis of the gross structure of the genes that would explain their behaviour. In fact, their organization appears to be quite dissimilar — for example, the gene for Kunitz trypsin inhibitor contains an 9.7-kilobase intervening sequence, while that for 11S storage protein is apparently colinear with its mRNA. Because no nuclear transcripts of these genes can be detected in cells which do not contain storage proteins (leaf cells, for example), it seems likely that their expression is regulated primarily at the level of transcription.

The storage proteins of barley (hordein) and maize (zein) are encoded by gene families which appear to contain at least ten to twenty highly homologous members. Interestingly, the expression of the entire family is drastically influenced by the activity of other genes (Larkins, Purdue University; Feix, University of Freiburg; Brandt, Carlsberg Laboratory, Copenhagen). Thus, mutations at the *lys 3A* locus of barley and the *opaque 2* locus of maize effectively abolish expression of the respective gene families. Again, this effect seems to be mediated at the transcriptional level. Clearly it will be interesting to compare the DNA sequences which lie upstream from the structural genes coding for these various storage proteins.

#### Chromosomal rearrangements

Several genes coding for abundant proteins (for example, the 11S storage protein and the Kunitz trypsin inhibitor of soybeans) appear to be located in the immediate vicinity of middle-repetitive DNA (Goldberg, University of California, Los Angeles). The evolution of analogous sequences in the genome of cereals was discussed at Heidelberg by R. Flavell (Plant Breeding Institute, Cambridge). By using cloned segments of repetitive DNA as

probes in *in situ* hybridization experiments, he has shown that the greatest concentration of several species of repetitive DNA maps at the ends of cereal chromosomes.

The detailed organization of these sequences, however, varies from species to species and even from chromosome to chromosome within a single species. Thus certain repetitive sequences are present more than  $10^6$  times in one secale species but fewer than 50 times in another; and several examples are known where different chromosomes of a single plant species carry different repetitive sequences at their ends. All of these observations are consistent with a model in which most of the non-coding DNA of cereal chromosomes 'turns over' relatively rapidly during evolution by a process of amplification and deletion, and new sets of repetitive sequences are created by the translocation of small pieces of DNA into new sites. Why repetitive sequences in plant genomes should be sequestered to the ends of chromosomes is not known.

Chromosomal rearrangements in plants are, of course, not limited to non-coding sequences. Burr (Brookhaven) has analysed mutations at the *shrunk* locus of maize caused by the transposable element *DS* (McClintock *Yb. Carnegie Instn Wash.* 51, 212–219; 1952) which causes chromosome breaks in the endosperm leading to dicentric chromosome formation. The *shrunk* locus codes for the enzyme sucrose synthetase, a partial cDNA copy of whose mRNA has been cloned. Using this as a probe in Southern hybridizations, Burr has been able to show alterations in the structure of the *shrunk* locus as a result of *DS* action, but because of the small size of the probe the extent of these alterations is not known. At least one of them involves deletion of part of the gene while others appear to result from insertion of sizeable tracts of DNA, perhaps multiple copies of *DS* itself.

#### Splicing

By contrast with this plasticity, sequences coding for some plant proteins have not changed appreciably over large spans of evolutionary time: for example, the leghaemoglobins of soybeans which, judged by their amino acid sequences, appear to be related to the ancestral haemoglobin of higher animals. The leghaemoglobins are encoded by a set of six separate genes, four of which are closely linked in a single 30-kilobase DNA fragment (Marcker, University of Aarhus). This arrangement is reminiscent of those found in the haemoglobin genes of mouse and man. The leghaemoglobin *c* gene contains two intervening sequences (between nucleotides coding for amino acids 34/35 and 103/104) which map at positions almost identical with those occupied by intervening sequences in mammalian haemoglobins. A third intervening sequence, not yet recognized in

any other haemoglobin, has been detected in leghaemoglobin *c* gene and has been mapped between sequences coding for amino acids 67 and 68. Whether this is a general feature of all six leghaemoglobin genes or is specific to the one copy which by chance has been cloned and sequenced is not known.

The DNA sequences at intron–exon boundaries have also now been determined for the phaseolin gene of beans (Hall, University of Wisconsin) — it contains three intervening sequences — and for the 23S ribosomal RNA gene of *Chlamydomonas* chloroplasts, which contains one (Rochaix, University of Geneva). All of these have the dinucleotides GT and AG at their 5' and 3' ends and correspond in many other respects to the common sequence across splice junctions in heterogeneous nuclear RNA of mammalian cells. Presumably, therefore, the mechanism by which transcripts of plant genes are spliced into mature functional RNAs is fundamentally similar to that in animal cells. There are indications that small 'adaptor' RNAs may be involved in splicing of mammalian RNAs (Lerner and Steitz *Proc. natn. Acad. Sci. U.S.A.* 76, 5495; 1979). A similar set of RNAs has now been discovered in green plants. Working with *Chlamydomonas*, Rochaix has shown that the 5.85S nuclear RNAs, and the 3S and 7S RNAs encoded by the chloroplast, are partially complementary to the sequences flanking the intron within the chloroplast gene coding for 23S ribosomal RNA. By pairing with the coding sequences in the precursor RNA, these small RNAs could cause the intervening sequence to loop out, making it more accessible to the enzymatic machinery involved in splicing.

#### Chloroplast genes

That chloroplasts carry genes essential for plant growth and survival has been known since the early years of this century. However, it is only during the past few years that chloroplast chromosomes have been physically dissected. Restriction endonuclease mapping and electron microscopy have shown that chloroplast genomes are always circular and large in size, varying from 135–210 kilobases in different plant species. A commonly occurring feature is the presence of two large, inverted and repeated segments, which in the case of maize are 22.5 kilobases in length. Within these repeats are arranged the genes for the chloroplast ribosomal RNAs in the order 16S–spacer–23S–5S. Spacers are a constant feature of all plant chloroplast genomes so far examined but vary in size from species to species. Within the genus *Oenothera*, insertions and deletions are found to occur within them. Because such alterations always occur in both copies of the spacers simultaneously, it seems likely that a mechanism exists which corrects one copy of the spacer against the other. Why this correction process occurs is not known.

The spacer regions are neither silent nor empty, containing genes for tRNAs and, in the case of *Chlamydomonas*, for 3S and 7S RNAs as well (Rochaix). Genes for additional species of tRNA (perhaps 30 in all) are scattered throughout the repeated and unique regions of the chloroplast genome. At least some of these are split by intervening sequences, which in *Chlamydomonas*, as in yeast, are located 1–2 bases distal of the anticodon loop (Kossel, University of Freiburg).

The sequences of the 16S, 23S and 5S genes of the chloroplast of several plant species are remarkably homologous with the corresponding sequences of *Escherichia coli* (Delius, Embl; Kossel; Rochaix). These highly conserved sequences include those near the 3' end of 16S rDNA as well as those immediately flanking the intervening sequences in *Chlamydomonas* 23S RNA. It therefore appears that part of the genome of present-day chloroplasts is derived from prokaryotic precursors.

Although chloroplast and nuclear genes are carried on separate pieces of DNA, at least two lines of evidence indicate that they are not evolving independently of one another. First, within the genus *Oenothera*, where five different types of chloroplast genome can be recognized by restriction-enzyme digestion, interspecific crossing can result in combinations of nuclear and chloroplast genomes not normally found in nature (Herrmann, Botanisches Institute, Dusseldorf). Often these hybrids are extremely unhealthy, displaying a bleached phenotype. Apparently, there is a mutual dependence between the two genomes such that chloroplasts are adapted to express in only one or a few nuclear backgrounds.

Secondly, the chloroplast genome is now known to code for more than 100 polypeptides. Some of the proteins found in the chloroplast, however, are not coded by the genome of the organelle but by the nucleus of the cell. Among these polypeptides are subunits of the thylakoid-located ATP synthetase of photosystems I and II, of cytochrome *f* and of the large subunit of ribulosebiphosphate carboxylase. These examples of cooperation between the chloroplast and nucleus argue strongly that the two genomes evolve as a binary pair.

The most detailed analysis of this phenomenon has come from studies of ribulosebiphosphate carboxylase — an enzyme built from two non-identical subunits. The larger of these subunits (LS) is coded by the unique region of the chloroplast genome, the smaller (SSU) by a nuclear gene. Both genes have now been cloned (the former from maize and the latter from pea) and sequenced. The mRNA for the small subunit is 760 nucleotides in length and is derived by splicing from a nuclear precursor some 200 nucleotides longer. It codes for a protein which contains at its N-terminal end at least 13 hydrophobic amino acids which are not

found in the mature subunit. Presumably they form a signal sequence which is cleaved off as the small subunit is transported into the chloroplast.

The LS subunit of ribulosebiphosphate carboxylase occupies a special place in the history of plant molecular biology in that its gene was the first to be mapped on the chloroplast genome. The entire gene, together with its flanking sequences, has been cloned and sequenced. The coding sequence is 1.6 kilobases in length and is colinear with the polypeptide. Located on the opposite DNA strand, some 300 nucleotides away, is the *his* gene. Despite their close proximity, the two genes are expressed in entirely different ways: that for *his* is expressed constitutively in both mesophyll and the neighbouring bundle-sheath cells of maize, while that for the large subunit is expressed efficiently only in mesophyll cells. It seems quite possible that this differential control is achieved at the level of transcription, since efficient and accurate transcription of the cloned LS gene *in vitro* by DNA-dependent RNA polymerase requires a 26K polypeptide isolated specifically from chloroplasts.

#### Plant vectors

The relative merits were discussed of two vectors which, potentially, can replicate both in plant and bacterial cells and also allow the expression of foreign genes in plants. Both have highly unusual properties. The double-stranded DNA of cauliflower mosaic virus has recently been sequenced and has been shown to contain single-strand discontinuities at unique sites — two in one strand and one in the other (Frank *et al.* Cell 21, 285; 1980). The viral DNA propagated in bacterial plasmids and therefore without discontinuities, retains its infectivity. However, the viral genomes arising from such infections and encapsidated into progeny virus particles reacquire single-strand breaks and the tangled topology typical of the viral DNA. Thus, neither the discontinuities nor the knotted topology are necessary for establishing infection but are formed in DNA which has been replicated in plants (Howell, University of California, San Diego; Hull, John Innes Institute, Norwich).

Only the DNA strand with the single discontinuity is transcribed during infection: at early times, a single species of RNA is detected with a molecular weight equivalent to that of one entire strand of the viral genome. Later, at least four other transcripts are found, the most prominent of which is about 2,200 nucleotides in length and codes for the inclusion body protein of molecular weight 65,000. Despite intensive searching, no sites have been detected in the genome which can accept foreign sequences without affecting the viability of the virus. Until such sites are found or until a system is established in which defective viruses can be complemented, cauliflower mosaic virus cannot be used as a vector.

The second potential vector is the Ti plasmid of the Gram-negative soil bacterium *Agrobacterium tumefaciens*, which induces crown gall tumours on most dicotyledonous plants. The Ti plasmid causes the neoplastic transformation of plant cells and the resulting transformed cells contain a segment of the Ti plasmid (T-DNA) which is 12–24 kilobases long and which is integrated and transcribed (Schell, Cologne; Chilton, Saint Louis). The boundaries of the integrated T-DNA have now been cloned from a line of transformed tobacco cells and analysed by DNA sequencing and hybridization. One of the clones examined contains the right and left borders of the T-DNA linked together; another contains the right end of the T-DNA linked to repetitive plant DNA (Zambryski, University of California, San Francisco).

These data suggest that the integrated T-DNA is arranged as a tandemly repeated element within repetitive plant sequences. However, they do not shed light on the mechanism by which the integration event occurs, nor do they prove that the T-DNA can become a stable part of the plant chromosome that can be transmitted through meiosis. It is the latter property which will determine whether T-DNA can fulfill its promise of serving as vector to carry foreign genes into dicotyledonous plants.

#### Viroids

Of all infectious agents so far discovered, viroids must rank among the most bizarre. The best characterized — potato spindle tuber viroid — is a single-stranded circular RNA molecule 359 nucleotides in length, with so much base-pairing that it is thermodynamically equivalent to double-stranded DNA. Several strains of potato spindle tuber viroid are known which differ greatly in their capacity to cause disease. Surprisingly, these strains differ from each other in only three nucleotides (Sanger, Giessen). How such seemingly insignificant changes can result in vast alterations in biological properties is unknown.

The mechanism by which viroids replicate has long been puzzling. Too small to code for an elaborate replication machinery, it had been assumed that, like retroviruses, they may integrate into the host genome and then be transcribed into new progeny viroids. This view has been challenged by two exciting findings. First, viroids are efficient *in vitro* templates for RNA polymerase II isolated from tomato callus or leaf cells. The product is equivalent in size to full-length viroid RNA (Sanger). Secondly, viroid replication in cells is inhibited by amanitin (Sanger; Diener, Beltsville). These results open the possibility that viroids replicate by an entirely novel mechanism in which the infecting RNA molecules are copied by the host enzyme which is normally responsible for synthesis of nuclear precursors to mRNA. □

# Electrochemistry and the geochemist

from H.A. Tourtelot

ELECTROCHEMISTRY deals with the relation of electron flow to chemical transformations that either create electricity or are caused by the flow of electric current. Geochemistry generally deals with Earth materials that are poorly conductive so that electrochemical transformations take place only within very short distances. In contrast, the term 'electrochemistry' seems to be used by geochemists to describe transformations involving highly conductive materials, such as sulphide minerals, and some others through which electrons travel easily. Transformations separated by considerable distances thus also are coupled by electron flow. Morris *et al.* describe in this issue of *Nature* (ref.1, p.250) such an electrochemical model for the formation of deep-seated iron ores.

Electrical phenomena around ore deposits were recognized long ago and provide the basis for the self-potential method of geophysical prospecting<sup>2,3</sup>. The electrochemical mechanism for self-potentials associated with sulphide ore bodies was examined by Sato and Mooney<sup>4</sup> based on the theoretical work of Pourbaix<sup>5</sup> and Latimer<sup>6</sup>. The paper by Sato and Mooney seems to be the chief introduction to geochemists of electrochemical theory applied to ore deposits. An ore body of conducting minerals connects oxygenated ground water near the surface of the Earth with ground water at a depth deficient in oxygen. This redox gradient is 'short-circuited' by upward electron flow in the conductive ore minerals<sup>7</sup>. Reduced compounds at depth thus are oxidized (electrons lost) and oxidized compounds near the surface are reduced (electrons gained). The circuit is closed by ionic conduction in the pore fluids around the

ore body. Cations move upwards towards the surface and anions move downwards. The diagram shown by Morris *et al.* (*Nature* this issue, p.251, Fig.1a) illustrates the general character of electrochemical systems as well as the specific system involved in iron ores where magnetite is the conductor of electrons, ferrous iron is oxidized to ferric at depth and oxygen is reduced to OH<sup>-</sup> at or near the surface.

Most economic iron ores consist of ferric oxide minerals that have formed largely by the oxidation of pre-existing ferrous minerals, such as magnetite, siderite, and iron silicates originally deposited in the Precambrian in an association known as banded-iron formation<sup>8</sup>. At some deposits, such as those in Brazil, formation of supergene ferric oxides that make up the ore is related to present and relatively recent weathering conditions<sup>9</sup>. As Morris *et al.* point out, some ferric-oxide ore deposits, such as those at Krivoy Rog, Russia and in the Hamersley Ranges, Western Australia, now exist at such great depths that their origin cannot be explained by the action of oxygenated ground waters, either now or at any time in the geological past. At Krivoy Rog, for example, oxide ores are found at depths as great as 2,400 m and in the Hamersley Ranges at depths greater than 400 m.

Explanation of the origin of the deep-seated iron oxide ores in the Hamersley Ranges by processes other than electrochemical are not offered by Morris *et al.* They suggest that electrochemical processes based on the conductivity of magnetite can be called upon to explain the origin of deep-seated oxidized banded-iron formation for ore deposits where the action of 'normal' oxidation processes cannot be comfortably accepted. Differing opinions, no doubt, will be expressed.

An earlier application of electrochemical theory to the genesis of ore deposits is that of Constantinou and Govett<sup>10,11</sup>. They considered the idea that electric potential differences within a sulphide body could cause movement of metals and could affect the distribution of elements in rocks overlying ore of the Cypress sulphide deposits. Experiments by Govett and Whitehead<sup>12</sup> showed that sulphides of different metals develop zoning patterns that are consistent with electrochemical theory and that are similar to the arrangement of minerals in some stratiform sulphide bodies such as Rammelsberg.

Another application of electrochemical theory is in exploration geochemistry. The electrochemical model for the formation of the Hamersley deep-seated iron deposits is

H.A. Tourtelot is a geologist with the US Geological Survey, Denver, Colorado.

based on work by Thornber, one of the co-authors with Morris *et al.*, on the supergene alteration of massive nickel sulphide deposits at Kambella, Western Australia<sup>13</sup>. Thornber's main effort was to explain supergene alteration of sulphides, according to electrochemical principles with a view to recognizing parameters useful in geochemical prospecting. He concluded that, under favourable conditions, *Eh* and *pH* patterns could indicate the presence of an oxidizing ore body.

Govett, taking a different approach to exploration geochemistry, suggested that metal contents in soils above some mineral deposits resulted largely from the upward flow of metal cations around a conducting sulphide ore body<sup>11</sup>. Later, he emphasized the importance of soil-slurry conductivities that give patterns at least as good as those from trace metals, that arise from the same electrochemical processes, and that are easier to determine in the field<sup>14</sup>. Patterns of conductivity are clarified if the measurements are corrected for H<sup>+</sup> concentrations that can be derived from *pH* measurements on the soil slurry. H<sup>+</sup> concentrations in soil slurries show typical anomalies in profiles across some ore deposits even though the deposits are covered by as much as 10 metres of glacial deposits<sup>15,16</sup>. Lithium gives a similar anomaly around an ore deposit in Norway probably, according to Bölviken and Logn<sup>17</sup>, because Li<sup>+</sup>, like H<sup>+</sup>, has high ionic equivalent conductance and should be one of the principal current carriers in an electrochemical system.

Many other processes besides electrochemical ones influence the formation of ore deposits as well as the zoning of metals around them, but an understanding of electrochemical effects may explain the origin of some ore deposits and provide a means for exploring for them. The work reviewed here has been done mostly by scientists in government and university research organizations, with extensive cooperation from mining companies to which the subject is of great interest and potential value.

100 years ago

The Jablochhoff light has been introduced by M. Hervé-Mangon into the Conservatoire. It will be fed by a Gramme machine, which the establishment has purchased for its constant use. The light will be placed in the amphitheatre, where M. Hervé-Mangon delivers, twice a week, his own lectures.

The lighting of the Victoria Station of the District Railway by means of the Jablochhoff electric light has been so successful that it has been also applied to the Charing Cross Station, and will shortly be introduced at Earl's Court.

## REVIEW ARTICLE

## Do waves limit turbulent diffusion in the ocean?

John D. Woods

Institute für Meereskunde an der Universität Kiel, Düsternbrooker Weg 20, D2300 Kiel 1, FRG

*Recent theoretical and observational studies of fluctuating motions in the stable interior of the ocean suggest that the rate of turbulent diffusion of scalars may be sensitive to the influence of waves on the energy balance of eddies and fronts. A new flow diagram is used to describe the turbulent cascades of energy and enstrophy in the ocean.*

REYNOLDS introduced the idea of separating motion into two parts, steady and fluctuating. In the ocean the gyre circulations can be thought of as the steady part and all the other motions as the fluctuating part. This division is clear in the climatological mean spectrum of oceanic kinetic energy (Fig. 1). The fluctuating part is normally divided into two categories.

(1) Wave-like motions that radiate energy and momentum through the ocean. Their propagation through the ocean can be described kinematically in terms of linear theory, plus resonant wave-wave interaction and dynamical interaction with the environment through which they pass.

(2) Advective-like motions that can only transport momentum and energy by advection of water particles from one place to another. The fluctuating motions in this category are often sufficiently energetic to require nonlinear description of their development with time. They can be further subdivided into (i) those motions that do not overturn isentropic surfaces (notably quasi-geostrophic eddies, and fronts); (ii) those that do overturn isentropic surfaces (billows, Langmuir cells, and the motion within patches of three-dimensional turbulence).

Many fluid dynamicists prefer to restrict the term 'turbulence' to the category (2ii). In this limited definition oceanic turbulence occurs only at the boundary layers, in deep-convection and in thin, transient blini in the interior. Oceanographers, however, talk about lateral diffusion in the interior of the ocean, occurring at rates ( $\sim 1,000 \text{ m}^2 \text{ s}^{-1}$ ) that cannot possibly be explained by the restricted picture of the fluid dynamicist. Oceanographers accept that the fluctuating motions in category (2i), those that do not overturn isentropic surfaces, demand statistical treatment in the spirit of turbulence theory. They too must be included in any description of 'turbulence in the ocean'. Recently, there has been increasing discussion about the need to include wave-like as well as advective-like fluctuations in any complete model of turbulence in the ocean designed to predict the rates of scalar diffusion. The basis for this is that the rate of turbulent diffusion depends on the kinetic energy density of the advective-like fluctuations which is limited by leakage of energy to waves that radiate the surplus energy away and dissipate it.

This article summarizes the main features of the conceptual model of ocean turbulence that emerges if waves play a significant part. The problem can be simplified by ignoring the well documented regional variation of turbulent kinetic energy. The method, a common one in turbulence theory, considers the statistics of fluid-dynamically important properties such as momentum and vertical component of vorticity, and in particular describes how their variances (kinetic energy and enstrophy, respectively) are transferred from one place to another and from one scale to another. The transfer from one place to another is achieved by advection (by mean circulation) and by radiation (of energy but not enstrophy) by waves. The transfer from one scale to another is called a cascade, which is a transfer

from one position to another in the wavenumber spectrum. We can also think of it as a flux of variance (energy, enstrophy, and so on) from one place to another in Fourier space. An integrated picture of turbulence in the ocean is developed by considering the budgets of kinetic energy and enstrophy, taking account of their fluxes through both physical and Fourier space by advection, radiation and cascading. To achieve this conservation laws are used which are like the laws of thermodynamics, but concerned with kinetic energy and enstrophy of the fluctuations of oceanic motion. There are important relations between the conservation laws of thermodynamics and turbulence theory. The most important law of ocean turbulence is that potential vorticity is conserved in adiabatic motion, that is, those that do not involve overturning and subsequent mixing of isentropic surfaces. Oceanographers have long relied on this law in developing theories of the gyre scale mean circulation; it is the basis of the Sverdrup balance. The law is also valid for fluctuating motions with scales ranging down to the order of 1 m in the interior of the ocean. This is because the vertical density gradient in the ocean interior is so large that the rate of kinetic energy input (of the order of  $\text{mW m}^{-2}$ ) is only sufficient to sustain intermittent overturning of isentropic surfaces on scales of 1 m or less. Between these rare and short-lived overturning events there is no three-dimensional turbulence; so, at any instant the interior of the ocean is in laminar flow almost everywhere. The law of potential vorticity conservation can be applied across the spectrum from the scale of the ocean basin down to the scale of overturning (of the order of 1 m). The climatological spectrum in Fig. 1 shows that this covers almost the whole of the range now under discussion. Conservation of potential vorticity is an approximation but the largest source of error—intermittent overturning and mixing of isentropic surfaces in the interior—is negligible for the present discussion. There is a striking similarity between this law and the law of conservation of relative vorticity in a strictly two-dimensional flow and many of the results of two-dimensional turbulence theory can be applied to oceanic turbulence. In discussing the statistics of the fluctuating oceanic flow we shall therefore use 'enstrophy' to describe 'variance of potential vorticity'.

### The gyres

In this article the main features of the new conceptual model of oceanic cascade physics are summarized using a new flow diagram presented in Fig. 2. On the left lies the largest scale of motion, the gyres of the upper ocean (A), driven by the wind through the agency of Ekman pumping (a). The gyres exhibit seasonal variation in response to the wind, but we can think of their streamlines as being steady compared with the fluctuating motions associated with the smaller-scale eddies, fronts, waves, and so on. The gyre circulation represents the mean flow, in

terms of Reynolds's division of a turbulent flow. Between adjacent gyres there are relatively sharp permanent fronts, characterized by maxima in both thermoclinicity and baroclinicity. The gyre streamlines pack closer in these frontal jets and in western boundary currents (for example, the Gulf Stream). Water particles take a decade or so to circulate around an upper ocean gyre. The size, location and number of gyres remains controversial<sup>2</sup>, so we are discussing the physics of the fluctuations without knowing the mean flow. This difficulty arises largely from uncertainty over the influence of the fluctuations on the mean motion; a first-order problem in both diagnostic and prognostic models of oceanic circulation.

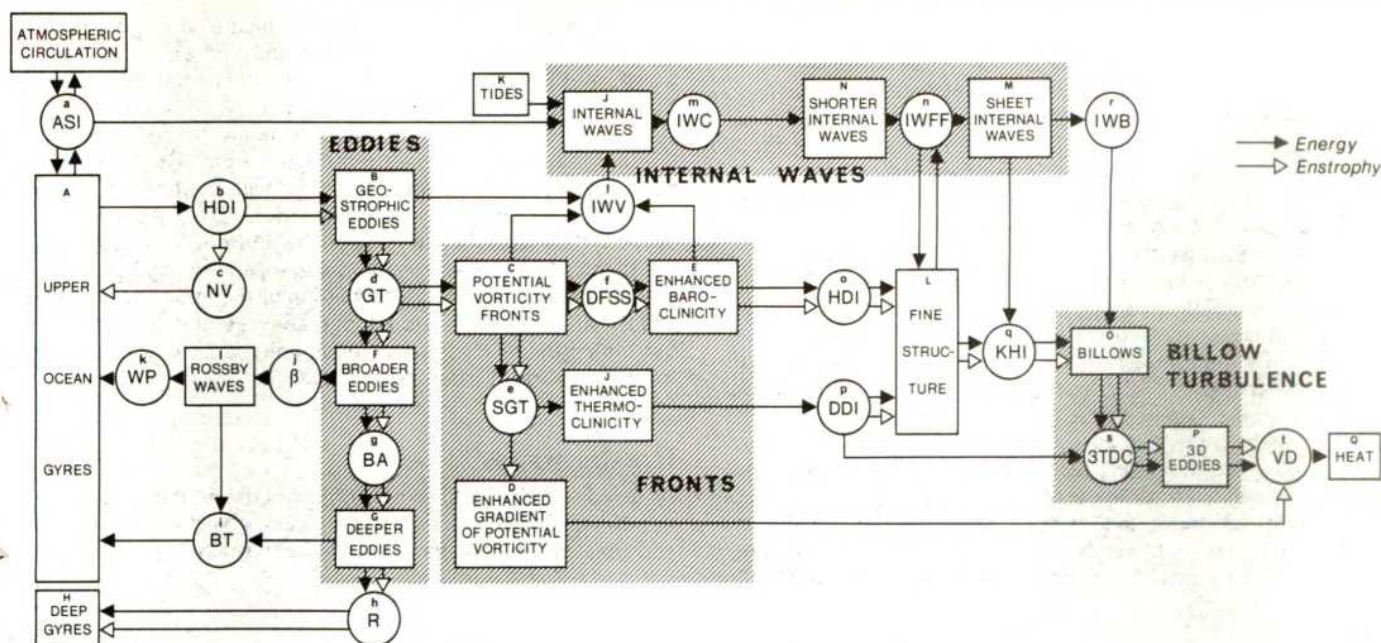

## The eddies

Hydrodynamic instability (b) of the gyres<sup>3,4</sup> and unsteady external forcing effects (wind, surface heat and moisture transfer) generate eddies (B) whose horizontal dimensions are of the order of 100 km and circulation speed of the order of 10 km

day<sup>-1</sup>. These eddies have a Rossby number ( $R_0 = U/Lf$ ) of the order of 0.01 and are, therefore, quasi-geostrophic. Field observations<sup>5</sup> during the 1970s have shown that such eddies occur widely (believed throughout the ocean) albeit with considerable regional variation (being strongest around the baroclinicity maxima of permanent fronts and western boundary currents). They are readily detected in oceanographic sections by the order of 100 m vertical displacement of isopycnals (and isotherms). The energy density in the spectral peak associated with the eddies (Fig. 1) exceeds that of the gyres by a factor of nearly 100; they are the energy-containing eddies of oceanic turbulence<sup>6</sup>. As detached eddies form from meanders, they interact with the gyre scale circulation in the upper ocean, influencing the pattern of mean streamlines<sup>7</sup>. There is some evidence<sup>8</sup> that, like their atmospheric counterparts<sup>9</sup>, eddy stress profoundly influences (c) the general circulation as though by negative viscosity. On the other hand, the eddies spread passive scalar anomalies along density surfaces at a rate equivalent to a (positive) diffusivity of  $\sim 70 \text{ km}^2 \text{ day}^{-1}$  (refs 6, 10).

**Fig. 1** A comparison of the climatological spectra for: a, turbulent kinetic energy in the atmosphere; b, turbulent kinetic energy and internal wave energy in the ocean based on recent observations. The space and time scales are in both cases approximate, being based on a mixture of eulerian and lagrangian estimates. (Figure reproduced from ref. 38.)

**Fig. 2** The new flow diagram for cascades of energy and enstrophy in the ocean. Letters on each box are indexed in the text. The following abbreviations have been used in labelling the circled processes: (a) ASI, air-sea interaction; (b) HDI, hydrodynamic instability (baroclinic and barotropic); (c) NV, negative viscosity, associated with baroclinic instability; (d) GT, geostrophic turbulence, which initiates the process of kinematic frontogenesis; (e) SGT, semi-geostrophic turbulence; (f) DFSS, dynamic frontogenesis at the (baroclinic) sea surface; (g) BA, baroclinic adjustment; (h) R, rectification of deep eddy enstrophy to give deep gyres; (i) BT, interaction with bottom topography; (j)  $\beta$ , interaction between eddies and Rossby waves; (k) WP, westward propagation of Rossby wave energy; (l) IWC, internal wave cascade of energy to higher wavenumbers; (m) IWCFF, interaction between internal waves and fine structure—internal wave strain produces fine structure, and fine structure permits very short trapped 'sheet' waves; (n) HDI, hydrodynamic instability of mesoscale fronts; (o) DDI, double-diffusive instability, leading to convection; (p) KHI, Kelvin-Helmholtz instability; (q) IWB, internal wave breaking (other than KHI); (r) 3DTC, three-dimensional turbulence cascade; (t) VD, dissipation of turbulent kinetic energy and enstrophy by molecular viscosity.

## Eddy decay

Observations of the streamline patterns associated with the eddies show a slow evolution with a lagrangian correlation time scale of  $\sim 50$  days (ref. 6); so, although they are the oceanic equivalent of the synoptic scale storms of the atmosphere, the eddies decay very much more slowly. (Rings, as distinct from eddies, decay an order of magnitude more slowly). One of the principal challenges in the study of oceanic turbulence is to develop a theory for this observed rate of decay. To decay, the eddies must lose both energy and enstrophy. The observed lifetimes indicate that this must occur at rates given, to order of magnitude, by the following example:

Eddy width

$$L = 100 \text{ km}$$

Rotation speed

$$U = 10 \text{ km day}^{-1}$$

Energy density

$$E = \frac{U^2}{2} = 50 \text{ km}^2 \text{ day}^{-2} \text{ per unit mass}$$

Enstrophy density

$$\Omega' = \frac{U^2}{2L^2} = 5 \times 10^{-3} \text{ day}^{-2} \text{ per unit mass}$$

Observed lifetime

$$T = 100 \text{ days}$$

Deduced dissipation rates:

$$(1) \text{ Energy } \quad \epsilon = 0.5 \text{ km}^2 \text{ day}^{-3}$$

$$(2) \text{ Enstrophy } \quad \eta = 5 \times 10^{-5} \text{ day}^{-3}$$

Ultimately the energy and enstrophy are dissipated by molecular viscosity ( $\nu = 10^{-2} \text{ cm}^2 \text{ s}^{-1}$  for seawater). Neglecting, for the moment, the complex processes shown in Fig. 2, we can estimate dissipation scales for the above example.

Dissipation scales:

$$(1) \text{ Energy } \quad l_e = (\nu^3 \epsilon^{-1})^{1/4} = 1 \text{ cm}$$

$$(2) \text{ Enstrophy } \quad l_n = (\nu^{1/2} \eta^{-1/6}) = 1 \text{ m}$$

In this primitive model, the eddy energy and enstrophy have to cascade through seven and five decades respectively of Fourier space before molecular viscosity can dissipate them, a requirement not significantly changed by the new model.

## The enstrophy cascade

The basic mechanism of the enstrophy cascade has been recognized for well over a decade, being closely related to the theoretical idealization of inviscid two-dimensional turbulence, in which particles retain their relative vorticity because there is no vortex stretching. Although the eddy motion in the interior of the ocean is not strictly two-dimensional it is—to a much better approximation—adiabatic, with the result that particles effectively retain their potential vorticity as they are swept around the complicated, fluctuating eddy streamline patterns. Below the wind-mixed layer and below the top few metres of the ocean, where the Sun warms the water diabatically, the most serious cause of error in the assumption of potential vorticity conservation arises from diabatic mixing by motion that overturns isentropic surfaces. Identifying this with billow turbulence we can estimate the magnitude of the error. The time scale for potential vorticity change due to diabatic mixing at rate  $K$ , in a region where the curvature of the vertical profile of  $N$  has a scale depth  $L_N$ , is given by  $T \approx L_N^2/K$ . Taking  $L_N = 0.1 \text{ km}$  for the oceanic thermocline, and estimating  $K$  from the above example

$$K = \epsilon N^{-2} = 5 \times 10^{-7} \text{ km}^2 \text{ day}^{-1}$$

where  $N = 1,000 \text{ day}^{-1}$ , we calculate that  $T \sim 2 \times 10^5$  days, which is so much longer than the eddy lifetime that we can neglect the effect of diabatic mixing. (The same calculation also justifies the assumption of potential vorticity conservation in gyre dynamics, for which the circulation time is of the order of 10 yr.)

## Fronts

The enstrophy cascade is, therefore, assumed to be adiabatic, and to proceed by lateral redistribution of potential vorticity<sup>12</sup>. As Batchelor<sup>11</sup> showed in the simpler case of two-dimensional turbulence, this leads to kinematic frontogenesis (d). A multiplicity of ever-extending, ever-thinning fronts (C) develop in the eddy contours of constant potential vorticity. This advective redistribution of eddy enstrophy has important consequences. First, the stretching of contours of constant potential vorticity into long, thin fronts introduces a local anisotropy involving sharp gradient of vorticity (D) and correspondingly large Rossby number in the cross-front direction. The resulting flow field is described by the semi-geostrophic equations used in studies of mesoscale fronts<sup>13,14</sup>. We therefore call this motion occupying the waveband 10 km to 1 m 'semi-geostrophic turbulence'. Most of the kinetic energy in each front is in its horizontal, quasi-geostrophic jet; however, the weak ageostrophic cross-front motion associated with the continuous thinning of the front is not horizontal, but rather it runs up and down the density surfaces inclined by the eddy baroclinicity. (Roughly speaking, the axes of the fronts lie tangentially to the adjacent eddies, like the bands of a spiral nebula.) At the sea surface, where density surfaces outcrop, this ageostrophic motion redistributes the strong near-surface thermoclinicity (due to solar heating) to give the characteristic modulation of sea surface temperature seen in

**Fig. 3** An IR image of the central Mediterranean Sea from NOAA 5 showing eddies sharply outlined by sea-surface temperature gradients at mesoscale fronts. (Photograph reproduced by permission of Dr P. Baylis, University of Dundee.)

satellite IR images (Fig. 3). At the same time, the kinematic frontogenesis (d, e) forced by the eddy motion interacts with the upper boundary (f) causing the frontal baroclinicity to peak strongly in the top few decametres, but to flatten below<sup>14</sup> (E), so that the kinetic energy of the semi-geostrophic turbulence becomes concentrated near the sea surface.

## Eddy expansion

As the eddy vorticity becomes teased out into fronts that extend beyond the original dimensions of the eddy, the mean eddy circulation also expands (F), carrying with it a small portion of the original eddy vorticity<sup>12</sup>. This lateral expansion is the oceanic realization of the reverse energy cascade in two-dimen-

sional turbulence theory. The broadening introduces baroclinic adjustment (g) with the result that eddy potential energy is transferred to eddy kinetic energy; the eddy rotates faster. At the same time, due to potential vorticity conservation, the vertical distribution of eddy energy tends to become more uniform; the eddy becomes more barotropic (G). This drives eddy enstrophy down into the deep ocean, where it can be rectified (h) to force deep gyre circulations<sup>15</sup> (H). As the eddies deepen they also begin to feel the bottom topography (i) producing the observed spatial inhomogeneity<sup>5</sup> and providing the link between the mean circulation of the upper ocean gyres and the much deeper bottom topography. Hence the steering of the Gulf Stream by bottom topography is a consequence of frontogenesis in the Gulf Stream eddies.

## Rossby waves

As an eddy broadens it soon approaches the limit beyond which the North-South difference in planetary vorticity across the eddy exceeds the mean eddy (relative) vorticity

$$\beta L > U/L$$

For the eddy in our example, this occurs when  $L > 200$  km. At this scale the eddy motion becomes influenced by the rotating Earth's sphericity (j) and energy begins to radiate as Rossby waves<sup>16</sup> (I), which propagate westwards. Streamline patterns derived from the MODE data exhibit this characteristic westward phase drift<sup>5</sup>. Compared with the full spectrum from millimetres to megametres, the eddies expand very little before Rossby wave radiation takes hold. The proximity of the scales at which the eddies first receive energy from the gyres and subsequently are converted to Rossby waves explains the narrowness of the observed spectral valley (not quite a 'gap') between the spectral peaks of the eddies and the gyres (Fig. 2). The Rossby waves powered by eddy expansion radiate energy to the distant ocean (possibly after scattering by bottom topography (i)), allowing mean circulation to be driven from a distance. The effect may be intensified at a western boundary, where energy tends to be trapped (k), accelerating the western boundary current and so contributing to the associated gyre circulation<sup>15,16</sup>.

## Internal waves

In classical inviscid, two-dimensional turbulence theory<sup>17,18</sup> all eddy energy is transferred to larger scale and eventually to the gyres, but in the ocean much of the energy cascades to smaller scale to be dissipated locally by molecular viscosity. The mechanism for this energy cascade cannot be turbulent frontogenesis for, although it efficiently cascades enstrophy to small scale, the associated energy cascade rate,  $\epsilon_t$ , is reduced in proportion to the square of the dissipation scale,

$$\epsilon_t = \eta_t l^2$$

For our example ( $\eta_t = 5 \times 10^{-5} \text{ day}^{-3}$ ,  $\epsilon = 0.5 \text{ km}^2 \text{ day}^{-1}$ ,  $l_e = 10^{-5} \text{ km}$ )

$$\epsilon_t = 5 \times 10^{-15} \text{ km}^2 \text{ day}^{-1} = 10^{-10} \epsilon$$

Thus, frontogenesis cannot dissipate much of the eddy energy. On the other hand, observations of ocean microstructure<sup>20,21</sup> are broadly consistent with the mean energy dissipation rate of our example ( $\epsilon = 0.5 \text{ km}^2 \text{ day}^{-1}$ ). How then does energy cascade from the eddies to small scale? One solution is that internal waves (J) extract energy from the eddies (and from the fronts) through the Reynolds stress they exert on the shear in the eddy/front flow<sup>22</sup>. The magnitude of the corresponding 'internal wave viscosity' (I) has recently caused controversy<sup>23,24</sup>, earlier estimates of  $0.1 \text{ km}^2 \text{ day}^{-1}$  being later revised downwards by a

factor of 10–100. The higher values were estimated on the basis of dynamical theory; the lower values are based on field observations. Nevertheless, the concept of internal wave viscosity is generally accepted, only the magnitude is in doubt. Taking an intermediate value of  $K_w = 0.005 \text{ km}^2 \text{ day}^{-1}$ , we estimate the rate of energy extraction from eddies with a mean vertical shear of  $10 \text{ day}^{-1}$  to be

$$\varepsilon_w = K_w (dU/dz)^2 = 0.5 \text{ km}^2 \text{ day}^{-3}$$

This is precisely the value of  $\varepsilon$  in our example, so we tentatively conclude that internal wave viscosity provides an important mechanism for extracting energy from the eddies.

Once the energy enters the internal wave spectrum it is believed to cascade efficiently by wave–wave interaction to the smallest scales of wave motion. This concept of an internal wave energy cascade is based on a combination of dynamical theory and empirical knowledge acquired during the past decade. In particular, observations have revealed a remarkable homogeneity of spectral form and level in the interior of the ocean<sup>25</sup>, with significant modifications in the upper ocean<sup>24</sup>. This is interpreted in terms of the universal saturation of the internal wave field<sup>23</sup>. Whenever additional energy is added at any scale (for example, by interaction with an eddy) the surplus is rapidly cascaded through the spectrum by wave–wave interaction (m) until it reaches the smallest scales, where the waves break, transferring the energy to three-dimensional turbulence<sup>24</sup>. Orlanski<sup>26</sup> has suggested that the shedding of surplus energy may occur even more efficiently by the enhanced large-scale wave strain causing small waves to break directly without a cascade through the whole wave spectrum. Either way, the large (1–10 km) internal waves that extract energy from the eddies/fronts pass it to small scales (~5 m) so efficiently that the energy is not propagated far from the point of injection before it is lost to breaking<sup>27</sup>. Energy removed from eddies by internal wave viscosity is dissipated locally, probably within some tens of kilometres. Note that the internal wave spectrum is not kept saturated by the energy loss from the eddies; there are other important sources, including air–sea interaction (a) and tides (K). Nor need the energy extraction from eddies come exclusively from internal wave viscosity: a significant part may come from the interaction of the eddies with bottom topography (not shown in Fig. 2). Finally the local character of energy dissipation by internal waves suggests that observed spatial inhomogeneity in the internal wave field, especially in the upper ocean, may reflect recent interactions with eddies and, especially in the upper ocean, with fronts<sup>28</sup> (E).

## Fine structure

Turning back to Fig. 1, we now arrive at the fine structure box (L). We have no theory for ocean fine structure just observations interpreted speculatively on the basis of analogy with laboratory experiments or otherwise. Some of the observed fine structure in density stratification can be explained by the transient straining (n) of the mean density field by internal waves<sup>29</sup>. The thermohaline characteristics of the fine structure suggests that water masses of different characteristics have intruded into one another in layers with vertical scales in the range 1–100 m and horizontal scales of up to several tens of kilometres<sup>24</sup>. Such structure is particularly sharply defined, with thin sheets (vertical scale ~10 cm) separating the layers, near fronts where the mean cross-front thermoclinicity is enhanced by kinematic frontogenesis<sup>28</sup> (J). A correlation between intrusions and meanders on fronts has suggested that the dynamical instability (o) of mesoscale fronts may provide an important mechanism for fine structure generation<sup>30</sup>. Theoretical studies of frontal instability showing complex vertical structure in the growing waves support this conjecture (M. K. MacVean, personal communication). An alternative proposal is that intrusions are driven by double diffusive convection (p), which is also most

effective in the enhanced thermoclinicity at fronts<sup>31</sup>. Most observations of fine structure comprise single profiles or sections, which do not provide the information needed to discriminate between these three main mechanisms: (1) internal wave straining (n<sub>1</sub>); (2) dynamical intrusion associated with frontal baroclinicity (o); (3) convective intrusion driven by the double diffusive release of latent static instability associated with frontal thermoclinicity (p). New techniques yielding time series of three-dimensional surveys of fine structure may help to overcome these limitations<sup>32</sup>.

The net influence of fine structure on the overall cascades of energy and enstrophy in the ocean remains uncertain, but its presence significantly modifies the details of the important transition from the cascades of frontogenesis and wave–wave interaction, in which isentropic surfaces are not overturned, to

Fig. 4 A simplified cascade diagram showing the principal paths by which oceanic eddy energy and enstrophy flow through the spectrum. The scale provides an indication of the approximate positions of the various classes of motion in the overall spectrum megametres to millimetres. The breadths of the cascade arrows are intended to suggest a possible distribution between competing paths.

the cascade of three-dimensional quasi-isotropic turbulence, in which they are. I envisage fine structure as the bridge between these two classes of cascade; not a single-span bridge—more like a complicated tropical bamboo construction. We may be able to develop theories for the statistical properties of ocean fine structure on the basis of some thermodynamic-like principle of optimum energy and enstrophy transfer between the three cascades. But for the present we must merely note elements of the fine structure mechanism. First, the internal wave community has drawn attention to the importance of fine structure in determining the high wavenumber cutoff of the internal wave spectrum<sup>33</sup>. Flow visualization observations have shown that the shortest internal waves—'sheet waves' (M)—are trapped on the thin sheets of enhanced static stability. It is not clear how they are generated; presumably by interaction (n<sub>2</sub>) between the fine structure and the shortest free internal waves. The trapped sheet waves are important because they and not the free waves are observed to break<sup>34</sup>. Breaking has been observed to result from Kelvin–Helmholtz instability (q), which occurs when the local Richardson number is <0.25.

$$Ri = \left| N / \frac{\partial U}{\partial z} \right|^2, \quad \left( \text{where } \frac{\partial U}{\partial z} \text{ is the shear} \right)$$

Kelvin–Helmholtz instability occurs infrequently when a sheet wave provides additional fluctuating shear (due to the orbital motion of the water particles) to supplement the more steady

shear of the fine structure currents<sup>34</sup>. Wave breaking may also occur independently of shear instability ( $r$ )<sup>35</sup>, but this has not been observed in the ocean.

## Billow turbulence

Kelvin-Helmholtz instability causes density (and isentropic) surfaces to overturn giving billows (O). Observations show that billows occur in rows on a sheet making blini several metres across in otherwise laminar flow<sup>36</sup> (defined here as being flow devoid of motion that overturns density surfaces). Empirical estimates of the instantaneous volume fraction occupied by billows in the upper ocean range from a few ( $\sim 5$ ) per cent in calm weather to an order of magnitude greater in stormy weather<sup>37</sup>. There is also considerable regional variability, with the highest concentrations found at intense currents and near fronts<sup>20,21,38</sup>. This intermittency must be allowed for as we follow the cascade of energy from the non-overturning motions (internal waves, fine structure currents) into the overturning motions of billow turbulence.

In making this transition we abandon the assumption of potential vorticity conservation and no longer consider the enstrophy cascade which becomes lost in the explosive generation of enstrophy by billow turbulence. The dual cascade of the mesoscale becomes fused into one as we pass into the microscale, thanks to the three-dimensional process of vortex stretching, which increases enstrophy at a rate that allows energy to cascade with no flux divergence until it becomes scattered into heat by molecular viscosity. The billows, the energy-containing eddies of three-dimensional turbulence in the interior of the ocean, are observed to be only a few decimetres high. They have Reynolds numbers of a few hundreds, barely sufficient to permit a modest inertial cascade of isotropic turbulence inside each billow ( $r$ ). The average energy cascade rate,  $\bar{\epsilon}_B$ , inside such tiny cylinders of three-dimensional billow turbulence is related to the mean energy flux  $\bar{\epsilon}_w$  through the internal wave cascade (neglecting contributions from sources other than the eddies) by the mean billow intermittency factor  $\bar{I}$ : that is

$$\bar{I}\bar{\epsilon}_B \equiv \bar{\epsilon}_w$$

For  $\bar{I} = 0.05$  and  $\bar{\epsilon}_w = 0.5 \text{ km}^2 \text{ day}^{-3}$ ,  $\bar{\epsilon}_B = 10 \text{ km}^2 \text{ day}^{-3}$ , which is typical of direct estimates from velocity microstructure measurements<sup>20,21</sup>. For this value of the billow turbulence energy cascade rate, the Kolmogorov microscale of molecule dissipation is

$$l_e = (\nu^3 \bar{\epsilon}_B^{-1})^{1/4} = 3 \text{ mm}$$

And the Ozmidov scale of largest overturning (taking  $N = 1,000 \text{ day}^{-1}$ ) is

$$l_N = (\epsilon_B / N^3)^{1/2} = 10 \text{ cm}$$

in good agreement with direct observation.

## Conclusion

The conversion of turbulent kinetic energy to heat ( $Q$ ) and the associated molecular dissipation of enstrophy ( $t$ ) complete the cascades begun with the creation of geostrophic eddies by instability of the mean gyre circulation. The cascades span 10 decades of Fourier space, a waveband one hundred million times broader than that of the most advanced prognostic model of ocean circulation. I have discussed the physics of processes that influence the mean circulation but which can never be resolved in such models. These unresolved processes must be treated statistically in the model equations—their effect on the large-scale circulation and distributions must be parameterized. Current practice relies on eddy transport coefficients invented by Boussinesq in the nineteenth century. Systematic investigation of the physics of ocean turbulence began in the 1960s and has progressed rapidly during the 1970s, with major advances in our understanding of eddies, waves, fronts, fine structure and billows. The new cascade flow diagram is not claimed to be correct, but it seems to offer the simplest conceptual model consistent with contemporary theoretical ideas and with the admittedly still primitive estimates of cascade rates. I anticipate and invite modifications. For example, the role of the ocean surface in modifying the cascade physics has scarcely been mentioned and the role of the seasonal change not at all. The interior of the ocean has been emphasized rather than the boundary layers, although these are likely to be important. Finally, according to the model, energy is extracted from the eddies by both internal waves and Rossby waves, but the latter only after the eddies have expanded by a factor of about two. If the internal wave viscosity is higher in some regions, a larger proportion of eddy energy will cascade to billow turbulence leaving less to feed Rossby waves, and vice versa. Does this imply less eddy expansion in regions of greater wave viscosity? If so, then there will also be less eddy deepening in these regions, and therefore weaker interaction with bottom topography and more feeble powering of deep gyres. But the wave viscosity depends on the internal wave saturation level and therefore on the mean static stability (and perhaps on the fine structure intensity). This suggests that the cascade physics described by the proposed new flow diagram should be inherently stable when applied to oceanic circulation models.

This article is based on a lecture presented at the IAPSO General Assembly, Canberra, December 1979 and uses material presented at the Second International Symposium on Turbulence in the Ocean (Liège, May 1979) co-sponsored by IAPSO and SCOR with support from UNESCO, IOC and IDOE. (Contributed papers are reported in ref. 39 and invited papers in ref. 40.) I thank Konstantin Fedorov, Terry Joyce, Sergei Kitaigorodskii, Dirk Olbers, Peter Rhines and Stewart Turner for helpful comments on an earlier version of the article.

# Latitudinal beaming of planetary radio emissions

Dyfrig Jones\*

Space Science Department, ESA, Estec, Noordwijk, The Netherlands

*The Voyager missions have revealed that jovian kilometric radiation (emanating from Jupiter's magnetosphere) is beamed away from the zenomagnetic equator. Results from GEOS 1 show that terrestrial non-thermal continuum or myriametric radiation is similarly beamed away from the geomagnetic equator. A mode-coupling mechanism is proposed such that measurements of the direction of propagation of the escaping O-mode radiations may allow the construction of the first high-resolution maps of the shapes of the equatorial plasmopause and Io torus.*

THE two Voyager spacecraft, which flew by Jupiter in March and July 1979, have shown that Jupiter's magnetosphere has many similarities to the Earth's as far as radio-wave observations are concerned<sup>1-4</sup>. Close parallels had already been drawn between jovian decametric emission, which has been observed from Earth for over two decades, and terrestrial kilometric radiation which has only recently been seen by Earth-orbiting spacecraft<sup>5</sup>. (Decametric and kilometric refer to the free-space wavelengths at which the radiations are predominantly observed.)

One wave component observed by the Voyager spacecraft—jovian kilometric radiation (JKR)—had seemed to have no counterpart within the Earth's magnetosphere. It is suggested here, however, that JKR is the analogue of the Earth's non-thermal continuum radiation<sup>6,7</sup>, the latter being termed terrestrial myriametric radiation (TMR). Both radiations seem to have their source in the intense electrostatic waves observed to be closely confined to the magnetic equators of both planets<sup>8,9</sup> in regions of large plasma density gradients—the Earth's plasmopause and the outer edge of the Io plasma torus.

## Terrestrial myriametric radiation

A particularly clear example of TMR was obtained for ~80 min on 4 March (day 63) 1978 by the GEOS 1 S-300 wave experiment which incorporates high resolution on-board correlators<sup>10,11</sup> and sweep frequency analysers<sup>12</sup> (SFAs). The spectrogram shown in Fig. 1 depicts signals from the 40 m tip-to-tip electric dipole as analysed by the SFAs. The start time is 02.50 UT and the end time is ~04.00 UT. During these observations, the satellite moved from ~5.4  $R_E$  to ~4.2  $R_E$ , where  $R_E$  is an Earth radius (6,370 km) and from a magnetic latitude of ~16°N to ~8°N. TMR is the striated emission seen in two frequency bands. Other natural emissions occur in the vicinity of the electron plasma frequency ( $f_{pe} = 9 \cdot 10^{-3} N_e^{1/2}$  kHz;  $N_e$  is the electron density per  $m^3$ ) and at the  $f_q$  'resonance' respectively. The increase in plasma frequency occurs because the spacecraft is moving towards the Earth and encountering increasing plasma density as the plasmopause is approached. Weak noise at lower frequencies is probably at  $3f_{ce}/2$  (ref. 8), where  $f_{ce}$  is the electron gyrofrequency ( $f_{ce} = 1.8 \cdot 10^3 B_0$  kHz,  $B_0$  is the magnetic field strength) which must also increase as GEOS 1 moves inwards. Clearly the low-frequency cut-off of TMR cannot be depended on to yield unambiguously the local plasma density, as has been suggested previously<sup>7</sup>.

The TMR increases in strength as the spacecraft approaches the plasmopause where intense radiation occurs in the vicinity of  $f_{pe}$  (where  $f_{pe}$  is the electron plasma frequency). The striations in the TMR are due to a beat between the satellite spin frequency ~0.2 Hz and the frequency ~0.04 Hz with which the SFAs are sweeping through the frequency range 0–75 kHz. The nulls in

the pattern occur when the dipole antenna used for receiving is aligned parallel to the direction of the emission's propagation, the antenna spin plane being approximately parallel to the equatorial plane. The fact that the pattern is so well-defined for so long is an indication that the radiation is arriving from preferred directions as GEOS 1 moves in towards the plasmopause. Such patterns have been used for direction-finding to locate the sources of TMR (ref. 7, and P. J. Christiansen, M. P. Gough and J. Etcheto, personal communication), and the sources were found to lie on the dayside plasmopause and on the morning magnetosheath<sup>7</sup>. It was also established that the radiation is significantly, if not predominantly, propagating in the left-hand ordinary (L–O) magnetoionic mode.

The hypothesis for the production of TMR considered here<sup>13,14</sup> is that electrostatic waves close to the upper-hybrid-resonance (UHR) frequency  $f_{UHR} = (f_{pe}^2 + f_{ce}^2)^{1/2}$  are the source of TMR. These intense UHR waves, which exist in a warm plasma, are tightly confined to within a few degrees of the magnetic equator at, and beyond, the Earth's plasmopause<sup>8</sup>. They are probably produced by a warm loss-cone component of the energetic electron distribution as outlined by Ronnmark *et al.*<sup>15</sup>. By virtue of their propagation into a slowly varying plasma density, it is suggested that their wave numbers decrease such that they access directly the cold-plasma Z-mode branch<sup>16</sup> of the dispersion relation, which is a natural extension of the warm-plasma branch. Ray-tracing of Z-mode waves show how subsequent access can be gained by these waves to magnetoionic window points<sup>17,18</sup>; these allow the direct coupling of energy to L–O mode waves which then propagate to lower density regions. These L–O waves are found to be beamed away from the geomagnetic equator by the presence of the local magnetic field.

## Jovian kilometric radiation

The Voyager spacecraft observed radio emissions in the frequency range 10 kHz–1 MHz, emanating from Jupiter's inner magnetosphere<sup>1-4</sup>. The emissions seem to suffer a distinct latitudinal beaming such that beyond the orbit of Io, a shadow zone exists with virtually no radiation seen within  $\pm 10^\circ$  of the zenomagnetic equator<sup>19</sup>. Furthermore, the latitudinal extent of the shadow zone increases with increasing wave frequency, so that the higher frequencies are beamed to higher magnetic latitudes. Polarization measurements<sup>4</sup> have shown that radiation seen north of the shadow zone, that is when the jovian magnetic north pole is tilted towards the spacecraft, is left-hand polarized, whereas that observed in the southern magnetic hemisphere is right-hand polarized; polarization is defined with respect to the direction of the wave-normal at the observer.

Two distinct and separate locations have been suggested as being possible source regions of JKR. The first source is assumed to lie along auroral magnetic field lines linked to the Io torus<sup>20</sup>. The torus is a region of enhanced plasma density believed to extend around Jupiter, threaded by the orbit of Io, and therefore

\*Present address: British Antarctic Survey, NERC, Madingley Road, Cambridge CB3 0ET, UK.

**Fig. 1** Diagrammatical representation of wave spectrogram obtained on GEOS 1 on 4 March 1978. Terrestrial myriametric radiation appears as inclined striations due to the preferential direction of arrival of the waves. Intense upper hybrid waves occur at  $\sim 30$  kHz after 04.00 UT.

lies close to the centrifugal and zenomagnetic equatorial planes. The auroral emission has been assumed to occur at  $2f_{pe}$  in the L-O mode<sup>20</sup>, and different frequencies would come from different altitudes above Jupiter, the higher frequencies being emitted from regions of higher densities closer to the planet. In this first theory, the Io torus acts merely as a passive obstacle to wave propagation, and ray-tracing in a model magnetosphere

**Fig. 2** Refractive index curves for the Z and O modes assuming that the gradient of electron density  $\nabla N_e$  is perpendicular to the magnetic field  $B_0$  as at the magnetic equator. A Z wave with initial wave normal  $n_z$  and corresponding ray  $r_z$  passes through the coupling point W to become an O wave finally having wave normal  $n_0$  and ray  $r_0$ , which make angle  $\alpha$  with the magnetic equator.

has shown that the equatorial shadow effect observed can be reasonably accounted for by this model, although the detailed extent of the shadow zone must depend on the assumed plasma density along auroral field lines. No specific mechanism has been suggested for wave emission at  $2f_{pe}$ , and as far as we know no unambiguous identification of  $2f_{pe}$  emissions has as yet been made within the terrestrial and jovian magnetospheres.

The other possible source is the Io torus itself<sup>2</sup>. To produce a shadow zone beyond the torus requires some sort of beaming mechanism, possibly inherent to the source. Another difficulty is an observation by Voyager 1, whose periapsis was at  $5 R_J$  which allowed it to traverse the torus centred at  $\sim 5.8 R_J$ . Peak densities within the torus were found to correspond to  $f_{pe} \sim 600$  kHz, whereas JKR extending up to  $\sim 1$  MHz has been detected. These results suggest that the Io torus may be unable to support emission at  $f_{pe} \sim 1$  MHz, the plasma frequency having been a possible candidate for the source emission. However, Voyager 1 probably did not pass through the region of peak density and Voyager 2, whose periapsis was at  $10 R_J$ , did encounter higher densities outside the torus than did Voyager 1 (ref. 4). Therefore plasma frequencies in the torus could exceed 1 MHz.

It is proposed here that JKR is created at, and beyond, the Io torus in a manner similar to that suggested for TMR. Within  $\sim 23 R_J$  of Jupiter, the Voyager spacecraft observed durable, intense UHR waves which, as was found at Earth, were very tightly confined to within  $\pm 2^\circ$  or less of the zenomagnetic equator<sup>9</sup>. However, much less is known about the Io torus than about the Earth's plasmopause and JKR may yield a significant insight into the characteristics of the torus at the magnetic equator.

## Theory

If a region of large density gradients<sup>13,14</sup> is located at the magnetic equator as at the plasmopause, then mode-coupling of Z-mode to O-waves could occur, and its consequences on the radiation can be illustrated by the refractive index surfaces in Fig. 2. The magnetic field  $B_0$  is shown with the electron-density gradient,  $\nabla N_e$ , assumed perpendicular to it as expected at the equatorial plasmopause. Z-mode refractive index surfaces have rotational symmetry about the magnetic field, but only one half is shown. The O-mode refractive index surfaces are also shown. The surfaces are for various plasma densities assuming the magnetic field to be constant; density in this refractive index domain increases towards the centre. The points W and W' are the window points through which Z waves can escape as O waves<sup>12,18</sup>. Snell's law requires that, during propagation,  $n \cos \theta$  remains constant,  $n$  being the modulus of the refractive index

vector in the direction of the wave normal, and  $\theta$  its angle with respect to the magnetic field. Therefore, a line parallel to the density gradient through point W represents the locus of the tips of the vectors from  $n_Z$  to  $n_O$  for the wave which couples from Z to O mode. The wave frequency, which is greater than the electron gyrofrequency, is assumed constant, the wave encountering the window when  $f = f_{pe}$ . Clearly, as the Z-O waves propagate through the coupling point to lower densities, the ray direction swings from  $r_Z$  to  $r_O$  and tends towards an angle  $\alpha$  with the equator, where  $\alpha$  is arcs in  $(f_{ce}/f_{ce} + f)^{1/2}$  (see ref. 17) and  $f_{ce}$  is the gyrofrequency at the window point, where  $f = f_{pe}$ . A similar ray will exist for window point  $W^1$ , and if mode coupling is the mechanism for TMR and JKR emission then the radiation would be beamed away from the magnetic equator at an angle  $\alpha$ . Figure 3 shows how  $\alpha$  depends on  $f_{pe}/f_{ce}$ , and for typical plasmaspheric densities, this ratio is in the region of 10 yielding an  $\alpha$  of  $\sim 17^\circ$ , although if the plasmapause moves to smaller radial distances such that  $f_{ce}$  increases, then  $\alpha$  may be much larger. Clearly if there is a large density gradient such that  $f_{pe}$  is increasing more rapidly than  $f_{ce}$ , then the higher frequencies from that region will be beamed to lower latitudes, and if the gradients are small so that  $f_{ce}$  increases more rapidly than  $f_{pe}$ , then the converse is true. If the plasma density gradient is radial, the beams will lie in the magnetic meridian plane; if it is not radial, the beams will lie in the plane containing the density gradient and magnetic field vectors.

### TMR ray paths

The terrestrial magnetospheric model used for the ray tracing has been described elsewhere<sup>21</sup>, although the plasmasphere model has been updated using information from GEOS 1.

Figure 4 shows the ray path in the magnetic meridian plane at  $4R_E$  of the Z-mode wave which couples to the O-mode, and which was in fact traced back from the coupling point. The arrows on the ray path indicate the directions of the wave normal. At S the wave normal is approximately parallel to the density gradient and perpendicular to the magnetic field. (The computations were stopped at S because the wave moves very slowly and the computation time becomes excessive.) The wave

**Fig. 4** The ray path in the magnetic meridian plane of a 40-kHz wave which starts at S with its wave normal, depicted by the small arrow, approximately perpendicular to the magnetic field and parallel to the density gradient. Mode-coupling occurs at the magnetic equator and the escaping  $O_R$  wave (solid line) propagates to free space at angle  $\alpha$  to the magnetic equator; the contour  $f_{pe} = 40$  kHz is shown. Reversing the wave-normal of the Z wave in the southern hemisphere allows coupling to occur at the other window to produce the  $O_L$  ray as shown in Fig. 2.

**Fig. 3** The variation of the beaming angle  $\alpha$  as a function of the ratio of electron plasma frequency to gyrofrequency,  $f_{pe}/f_{ce}$ .

normal in this direction is very important because electrostatic UHR waves can propagate<sup>15</sup> without damping only with their wave normals close to perpendicular to the magnetic field. Therefore if the warm-plasma electrostatic waves propagate to link on to the cold-plasma Z-mode, it might be expected that at that point (S) the Z wave-normal will be as shown. The possible significance of such Z wave-normals, parallel to the density gradient, had been pointed out previously<sup>22</sup>. The Z ray eventually reaches the coupling point with its wave normal parallel to the magnetic field, and the O ray which couples from it moves to lower plasma densities at an angle  $\alpha$  to the geomagnetic equator. This ray,  $O_R$ , will be observed to be right-hand polarized by a satellite; the ray  $O_L$  from the other window point will be observed to be left-hand polarized. Unfortunately, no polarization measurements of TMR have yet been performed.

It is significant that had the initial Z wave normal at S been such that the window had been just missed, the Z ray would propagate symmetrically about the equator, becoming electrostatic again, with its wave normal reversed, and possibly yielding its energy back to the charged particles on passing once more into the equatorial interaction region. Note that the latitudinal excursion of the Z ray which couples out is only  $\sim \pm 1^\circ$  from the magnetic equator, which was found to be approximately the extent of the intense UHR waves seen on GEOS and other spacecraft.

**Fig. 5** Beams of O radiation for different frequencies assuming each has coupled out at the levels corresponding to  $f = f_{pe}$ . The plasma frequency contours are labelled 15–120 kHz. The GEOS 1 track is shown and the inset shows the type of spectrogram observed by a satellite moving along track AA'.

If one assumes that the window points are distributed  $\pm 0.5^\circ$  about the Equator, then the resulting beams of TMR in the Northern Hemisphere are as shown in Fig. 5; identical beams exist in the Southern Hemisphere. The beams for a whole range of frequencies  $f$  are illustrated, each being assumed to have penetrated the window at the relevant level where  $f = f_{pe}$ . The track of GEOS 1 corresponding to the event on 4 March 1978 is also shown. The plasmopause in the model used in the ray-tracing needs to be moved inwards to slightly smaller radial distances. For a given frequency the latitudinal beam angle  $\alpha$  will then increase because  $f_{ce}$  increases, and  $f_{pe}/f_{ce}$  decreases. That the TMR above 45 kHz in the GEOS-1 spectrogram remains virtually unchanged throughout the time of observation indicates that the satellite was moving within and parallel to the beam at those frequencies. A satellite moving along track AA' in Fig. 5 would record a spectrogram similar to that shown in the inset. However, much more complicated spectrograms can be envisaged depending on the satellite track chosen. (An example of a TMR spectrogram in which the frequency decreases as the satellite moves inwards towards the plasmopause may be seen in Fig. 7 of ref. 23.) The frequency bandwidth of the TMR received at a given satellite position is indicative of the width of the beam, and the assumed  $\pm 0.5^\circ$  latitudinal extent of the source seems to be approximately that required to explain the GEOS 1 spectrogram.

### JKR ray paths

Ray-tracing has also been performed in a model jovian magnetosphere assuming that UHR waves at the Io torus and beyond are responsible for JKR. The model magnetosphere, detailed elsewhere<sup>24</sup>, is largely similar to that of the Earth's taking into account the opposite polarity of the magnetic dipole, the different magnetic field strength and the existence of the Io plasma torus. If the Io torus has a low-curvature rounded outer edge at the equator, the O waves, which come from the proposed coupling process, will be beamed in a similar manner to those from the Earth's plasmopause. Because Jupiter's magnetic dipole is inverted compared with that of the Earth's, the beam which would be observed in the northern magnetic hemisphere would be left-hand polarized as seen by a spacecraft. This is opposite to what was observed by the Voyager spacecraft, and to

adjust the model to account for this, a distended torus is necessary, as shown in Fig. 6. The contours of constant plasma density are labelled with their corresponding plasma frequencies and the ray paths are shown for different wave frequencies, assuming that mode-coupling has occurred at  $\pm 0.5^\circ$  latitude. Provided the torus distension tilts with the tilting magnetic field, a spacecraft located at a given centrifugal latitude will observe tapered emissions of the type seen by the Voyager spacecraft; as the magnetic latitude of the spacecraft increases, higher frequencies are observed, and a shadow zone exists within  $\sim \pm 10^\circ$  of the magnetic equator.

This beaming of JKR depends on the shape of the torus, distension at the equator and hence a detailed analysis of JKR could yield valuable information on those torus regions not visited by the Voyager spacecraft. The rocking of the torus by the magnetic field is to be expected as the Io torus is believed to contain anisotropic charged particle distributions favouring large pitch angles, and any gradual tilting of the magnetic field would cause the particles to be moved bodily with it.

Also, if there were propagation through the other window point, then in Fig. 6 the result would appear as very narrow beams (dashed lines) going to high latitude as shown for a source at  $8 R_J$ . Whether these exist probably depends on the ray-paths of the corresponding Z-mode waves. Figure 7 shows the ray paths of Z waves which would couple through the two windows. The coupling is assumed to occur at  $8 R_J$  at latitude  $0.5^\circ$ ; also shown are the resulting O-mode rays,  $O_L$  going to a low latitude and  $O_R$  to a high latitude. Data from the Voyager Planetary Radio Astronomy experiment should confirm whether the high-latitude beams exist. As Voyager 2 moved inwards towards the torus the plasma wave experiment observed that at about  $46.5 R_J$  the Northern source split into two<sup>3</sup>, and this effect may be produced by a single narrow beam which is cut twice by the spacecraft—once as its magnetic latitude increases and once as it decreases. On Voyager 2 the strong JKR at  $\sim 17$ –56 kHz disappeared at  $\sim 33 R_J$ , indicating that the source region for these frequencies had been passed, and clearly there was a fairly large density gradient at  $\sim 33 R_J$ , such that the plasma frequency

**Fig. 6** The low-latitude limits of the 'main' beams of jovian kilometric radiation showing the latitudinal dependence on frequency. The plasma density contours representing the distended Io torus are labelled according to plasma frequency (50–400 kHz). The narrow beams to high latitudes are from propagation through the second coupling point (see text), the L and R depicting left-hand and right-hand polarization respectively as observed by a spacecraft.

**Fig. 7** Details of ray paths close to the coupling region. ES shows where the upper hybrid waves are electrostatic. One Z ray propagates to  $-0.4^\circ$  magnetic latitude before it reaches the coupling point at  $+0.5^\circ$  latitude, subsequently propagating as the  $O_R$  ray going to high latitude. The other Z ray turns at  $+0.65^\circ$  latitude and becomes the  $O_L$  ray. For reference the  $L = 8$  magnetic field line is shown as is the plasma frequency contour corresponding to 186 kHz. The wave frequencies are all 196 kHz.

increased rapidly from 17 kHz to above 56 kHz in a relatively short distance. Perhaps narrow-band JKR sometimes observed as a stronger emission within wide-band JKR has its source in such large density gradients, which increase the window width, thereby allowing the escape of more Z-mode energy<sup>18</sup>. There has been some controversy as to the identification of the UHR frequency on Voyager 2 (refs 3, 4) and, on the basis of the theory proposed here, the 56 kHz UHR frequency was at  $\sim 30 R_J$  and the UHR frequency at  $\sim 10 R_J$  was probably  $\sim 193$  kHz. However, in a highly distended torus latitudinal variations are an important factor when interpreting the *in situ* density estimates made by the Voyager experiments.

## Discussion

The theory that intense electrostatic UHR waves coupling to L-O waves through the Z-mode are the source of JKR and TMR can account for many characteristics of the radiations. Detailed ray tracing of the electrostatic UHR waves in a realistic magnetospheric model and calculations of the width of the coupling windows are underway to confirm some features of the hypothesis, and to calculate the efficiency of the processes. The powers of TMR and JKR previously estimated on the basis of isotropic emission will have to be correspondingly reduced. Limiting the symmetrical Z-mode ray paths to  $\pm 1^\circ$  of the magnetic equator is believed to be significant and may be a crucial factor in the instability and in the energy exchange between waves and particles at the equator. That the UHR waves can access the Z-mode branch may indicate where exactly on the warm dispersion branch the UHR waves are produced<sup>25</sup>.

Note also that the confinement of UHR waves and associated particle distributions<sup>8,26</sup> may allow the first determination of the actual position of the magnetic equator, which would be very important within the context of other types of equatorially produced emissions, such as whistler-mode 'chorus'<sup>27</sup>.

A more detailed analysis of Voyager wave data should yield much new information on the Io torus. For example, the theory proposed here would predict that lower-frequency long-lived features of JKR should exhibit less co-rotation than higher frequencies because the former have their source at larger radial distances.

An important consequence of the theory, because the propagation windows are only a few degrees wide in practice<sup>18</sup>, is that JKR and TMR will be beamed away from the source region such that the rays lie very close to the plane containing the magnetic field and the density gradient vectors. This provides a powerful diagnostic technique allowing one to map the shapes of the plasmopause and Io torus in their respective equatorial planes by performing direction-finding measurements on the radiation. JKR shows long-lasting co-rotating features which reappear at approximately the same longitude for many jovian rotations. The Earth's plasmopause may co-rotate without large changes in its shape provided that one is not in regions affected temporally by large substorm electric fields<sup>28,29</sup>. High-resolution direction finding (DF) measurements are being performed using GEOS and ISEE data and the results will be reported later.

These comments on the plasmopause source are equally valid for the other source of TMR—the morning magnetosheath. Gurnett *et al.*<sup>30</sup> have reported ISEE observations of narrow band emissions near the electron plasma/upper hybrid frequencies in this region of the magnetosheath and I suggest that the energy in these waves also escapes as L-O mode radiation in a manner similar to that proposed for the plasmopause source. The magnetosheath magnetic field and plasma flow velocities are continuously changing depending on the direction of the interplanetary magnetic field and solar wind velocity and it is more difficult to determine the shape of the magnetosheath on the basis of the DF measurements. However, in stable conditions and with high time-resolution DF data it may be possible to map the magnetosheath and to see the propagation of irregularities and large-scale waves within it.

Finally, I re-emphasize that the determination by spacecraft of the local plasma density from the sharp low-frequency cut-off of TMR should be treated with caution. Clearly the cut-off is often due to beaming effects and bears no relation to the local plasma frequency at the satellite except in that it provides an upper limit to it. This may be equally valid for the low frequency jovian emissions tentatively identified as non-thermal continuum, which were detected by Voyagers 1 and 2 on their outbound passes<sup>1,3</sup>, and which were observed also to have a shadow zone at the magnetic equator.

I thank K. G. Budden, P. Christiansen, J. Etcheto, C. Goertz, P. Gough, R. Grard, D. Gurnett, R. Helliwell, R. Herring and M. J. Rycroft for stimulating discussions, R. M. Laws for support, and E. Gershuny, M. Trischberger and C. Boucher for computing assistance.

# Greenland ice sheet evidence of post-glacial volcanism and its climatic impact

C. U. Hammer, H. B. Clausen & W. Dansgaard

Geophysical Isotope Laboratory, University of Copenhagen, Haraldsgade 6, DK 2200 Copenhagen N, Denmark

*Acidity profiles along well dated Greenland ice cores reveal large volcanic eruptions in the Northern Hemisphere during the past 10,000 yr. Comparison with a temperature index shows that clustered eruptions have a considerable cooling effect on climate, which further complicates climatic predictions.*

HISTORICALLY, man has often been directly influenced by volcanic eruptions: for example Mont Pélée (Caribbean, 1902), Krakatoa (Indonesia, 1883), Tambora (Indonesia, 1815), Laki (Iceland, 1783), Vesuvius (Italy, AD 79), and Thera (Santorini, ?). Other great eruptions have been observed only by the associated optical phenomena in the atmosphere caused by volcanic aerosols, for example AD 1601–02 (ref. 1) and 44 BC (ref. 2). But, before AD 1600 most volcanism was not recorded, and not even noticed outside the regional areas that suffered from the direct impact of the eruptions.

However, indirect impacts may be expected, because great volcanic eruptions inject huge amounts of silicate micro-particles and acid gases into the stratosphere. The main effect of the silicates is probably to heat up the stratosphere by absorption of solar radiation<sup>3,4</sup>, but they disappear by settling during the first few months<sup>5,6</sup>. At the same time a sulphate aerosol, mainly sulphuric acid, is building up from SO<sub>2</sub> to become the dominant aerosol<sup>6,7</sup>, the main effect of which seems to be cooling the lower troposphere by back scattering of solar radiation<sup>3,4</sup>. Most of this information has been obtained by directly monitor-

**Fig. 1** Mean acidity of annual layers from AD 1972 to 553 in the ice core from Crête, Central Greenland. Acidities above the background,  $1.2 \pm 0.1$   $\mu\text{equiv. H}^+$  per kg ice, are due to fallout of volcanic acids, mainly H<sub>2</sub>SO<sub>4</sub>, from eruptions north of 20°S. The ice core is dated with an uncertainty of  $\pm 1$  yr in the past 900 yr, increasing to  $\pm 3$  yr at AD 553 (ref. 10), which makes possible the identification of several large eruptions known from historical sources, and the accurate dating of the Icelandic Eldgjá eruption shortly after the settlement that was completed AD 930.

**Table 1** Magnitudes (in terms of global acid fallout) of some volcanic eruptions north of 20°S, roughly estimated from the acidity of annual layers in ice cores from Greenland

| Volcano               | Location    | Year of eruption<br>AD | Volcanic acid<br>fallout in<br>Greenland<br>(H <sub>2</sub> SO <sub>4</sub> + HX)<br>kg km <sup>-2</sup> | Latitude<br>correction<br>factor* (1/F) | Global acid<br>fallout<br>(H <sub>2</sub> SO <sub>4</sub> + HX)<br>(× 10 <sup>6</sup> tons) |

\* See ref. 8.

ing the atmosphere in the years after the few great eruptions that have occurred in the past 20 yr, but this period of observation is obviously too short to allow any conclusion as to a possible persistent climatic effect of volcanic activity.

In the Northern Hemisphere (north of 20° S), the Greenland ice sheet is a rich source of information on past volcanism. This is not due to deposition of volcanic micro-particles<sup>8</sup>, as these are apparently too large and/or too few to reach the high-altitude regions of the Greenland ice sheet in amounts that significantly raise the (continental) dust concentration background. However, volcanic acids in snow layers deposited shortly after a large volcanic eruption can be detected—as elevated specific conductivities measured on melted ice samples<sup>8</sup>, or as elevated acidities revealed by an electric current through the solid ice, when pulling a simple pair of electrodes (voltage difference ~1,250 V) along a clean cut surface of an ice core<sup>9</sup>. We used the latter method because it is fast, non-destructive and more selective, the current being almost entirely determined by the protons from the strong acids.

### The Crête acidity record

A 404-m long ice core from Crête, Central Greenland (71° N, 37° W), was recovered in 1974 by US Cold Regions Research Engineering Laboratory under the American-

Danish-Swiss Greenland Ice Sheet Program (GISP). It has been dated to an accuracy of ±1 yr through the past 900 yr and to ±3 yr at the oldest annual layer deposited AD 553 (ref. 10).

Electrical measurements on the solid ice provide the acidity record shown in Fig. 1, except for the upper porous part of the core (back to AD 1840), where the acidity values are based mainly on pH measurements on melted samples. Some of the very low values recorded since AD 1840 may be due to the difficulty of making a proper correction for CO<sub>2</sub>-induced H<sup>+</sup> in water of low acidity. The same reason may have caused a few small signals to be omitted in the uppermost part of the record.

Low-latitude eruptions generally show up with a time lag of ~1 yr due to the long travel time of the aerosols before deposition in Greenland. Some of the easily identified eruptions are denoted in Fig. 1. The layers of highest acidity coincide with internal reflection horizons in radio-echo sounding<sup>8,11</sup> and are thus recognizable all over Greenland.

The increase of the acid concentration in ice layers containing debris from a high northern latitude eruption can be used to estimate the global H<sup>+</sup> fallout by applying the same latitudinal distribution pattern observed for <sup>90</sup>Sr fallout from high northern latitude bomb tests. In 1962, the global fallout of <sup>90</sup>Sr (mainly from the Soviet tests in 1961) was 1.2 MCi which was 8.6 × 10<sup>8</sup> and 6.4 × 10<sup>8</sup> times the fallout per km<sup>2</sup> at Crête and Camp Century, respectively. Applying this factor to the time-

integrated fallout of volcanic acids per  $\text{km}^2$  from a given eruption gives the magnitude of the eruption in terms of acid-gas injection into the stratosphere. The fallout from mid-latitude ( $20^\circ\text{--}50^\circ\text{N}$ ) or low-latitude ( $20^\circ\text{S--}20^\circ\text{N}$ ) eruptions should be multiplied by factors of 2 or 3, respectively, to account for the spread of the eruption cloud during the travel to high northern latitudes, judged from fallout data (more extensive than in ref. 8) on debris from bomb tests outside the polar region. Magnitude estimates on several eruptions listed in Table 1 could easily be wrong by a factor of 2 for several reasons. For example, they may be underestimated, because some acid may have been neutralized before deposition, and in the case of Tambora, a higher fraction of the acid gases than during the explosive Krakatoa eruption may have remained in the troposphere where they were washed out at low latitudes. On the other hand, a high tropospheric wind pattern, favourable for deposition of volcanic acids in Greenland, may lead to an overestimation, particularly in the Icelandic eruptions.

**Fig. 2** The acid fallout (black curves; scale on top) from two long volcanic eruptions, found in annual layers at Crête. *a*, The Tambora eruption in Indonesia began AD 1815, and the fallout in Greenland peaked in 1816, "the year without a summer" (ref. 12). *b*, The  $\delta(^{18}\text{O})$  curve to the right shows that the fallout from an eruption in AD 1600 or early 1601 at an unknown locality lasted to the end of 1602. The  $\text{NO}_3^-$  concentration (shaded curve to the left) varies seasonally, but it was not above normal shortly after the supernova 1604 (see ref. 16).

Most of the eruptions recorded in the Crête core (Fig. 1) and listed in the upper part of Table 1 will now be considered individually.

Krakatoa (1883,  $6^\circ\text{S}$ ) and Tambora (1815,  $8^\circ\text{S}$ ) are revealed by relatively low signals due to the long distance to Greenland. Figure 2*a* shows that the acid fallout from the Tambora eruption peaked in mid 1816, "the year without a summer"<sup>12</sup>.

Laki (1783) and Eldgjá (tenth century) are the two highest signals in the record; revealing the two greatest eruptions in Iceland since the landnam (settlement) of 875–930, perhaps since the last glaciation. The fallout from Laki (1783) has been detailed elsewhere<sup>8</sup>. The exact year of the Eldgjá eruption does not appear in Icelandic annals, but according to Thorarinnsson (personal communication, and ref. 13) the eruption took place some time during or shortly after the landnam, although not later than AD 950. The eruption is identified (at AD  $934 \pm 2$ ) in the Crête record with high certainty, because (1) the eruption was of the same magnitude as Laki (1783), at least  $10 \text{ km}^3$  of lava, which is more than any other lava extrusion on Earth in historical time, and (2) there is no other signal comparable to that of Laki (1893) in the said period.

Hekla (1104) is the greatest Hekla eruption (H1) in Icelandic historical time, that is, in the past thousand years. The annals generally date it at 1104, and "the winter of sand-rain" 1104–05 is discussed which suggests that the eruption began late in 1104. In a detailed acidity record<sup>9</sup> the acidity increases upward from the top of the annual layer previously dated at 1104 by the  $\delta$  method, and Fig. 1 shows an acidity peak in 1105, which is strong evidence that the time scale is correct at around AD 1100.

Most signals, particularly before AD 1600, are due to unknown eruptions somewhere in the Northern Hemisphere. The three strongest such signals are those in AD 1601–02, 1258–59 and 623–24 (see Fig. 1). The eruption corresponding to the first signal caused "a constant haze over southern Scandinavia in 1601. . . The Sun and Moon appeared 'reddish, faint and lacked brilliance' in central Europe all through the year 1601 and up to the end of July 1602" (ref. 1). Figure 2*b* spans the period 1599–1608, according to the dating based on counting seasonal  $\delta$ -variations downward from top of the core. The  $\delta$ -curve is first order corrected for smoothing by diffusion<sup>14</sup>. The acidity curve in the middle shows that the acid fallout lasted from the beginning of 1601 to the end of 1602. The location of the 1601–02 eruption cannot be deduced from these measurements, but the high peak of the signal suggests mid- or high latitudes (Alaska, Kamchatka?) because otherwise a low-latitude eruption causing this amount of fallout in Greenland would have to be of the Tambora class and could hardly have escaped the attention of the early colonialists. The  $\text{NO}_3^-$  concentration curve in Fig. 3 measured on melted samples<sup>15</sup> shows that  $\text{HNO}_3$  did not contribute to the elevated acidity signals in 1601 and 1602. Nor did the  $\text{NO}_3^-$  concentration increase above normal in 1604 and 1605 (the  $\text{NO}_2^-$  concentration was close to zero), which heavily influences the hypothesis of elevated nitrate production in the atmosphere during the supernova observed in 1604 (ref. 16), as will be discussed elsewhere<sup>17</sup>. Note that the  $\text{NO}_3^-$  concentration exhibits persistent seasonal variations (compare with the  $\delta$  curve, which usually peaks in late summer), suitable for stratigraphic dating independent of volcanic eruptions. The  $\text{NO}_3^-$  summer peak may be due to the nitrate production in the atmosphere being determined by the intensity of the solar radiation, but the explanation is probably more complicated.

The third highest signal in the record spans three years and peaked in 1259. It cannot be ascribed to any Icelandic eruption, because the closest one in time (1262, probably a minor eruption of Katla; Thorarinnsson, personal communication) is not within our uncertainty limits of about one year. The eruption must also have been large, because the integrated fallout is at least of the same order as that of Laki (1783).

Before AD 900 the volcanism revealed in the Crête record cannot be ascribed to any known eruptions. The highest signal on an annual basis is that of 623, and the absolute maximum acidity ( $\sim 10 \text{ } \mu\text{equiv. H}^+ \text{ kg}^{-1}$ ) on a more detailed record occur.

red in 757. We doubt whether any of these signals were caused by the great eruption in the Yukon basin of Alaska some 1,400 yr ago, because an Alaskan eruption, estimated at 50% of Tambora (1815) in terms of ash production<sup>18</sup>, would be expected to cause considerably higher acid fallout in Greenland than indicated in Fig. 1. It is more likely that the Yukon eruption will show up if the acidity record is extended beyond AD 553—the year of deposition of the oldest layer in the 404-m long Crête core.

### The Camp Century acidity record

The Camp Century, north-west Greenland (77° N, 61° W), ice core is the only one reaching from the surface to the bedrock in Greenland. The core is 1,390 m long, corresponding to 1,367 m of ice equivalent, and the deepest part of it is >100,000 yr old<sup>19</sup>. Unfortunately, there is a gap of ~510-yr between the oldest layer in the Crête ice core and the youngest part of the Camp Century core that is in sufficiently good physical condition for continuous acidity analyses (only a few outstanding events since AD 43 have been safely identified, for example, 1259 and Laki 1783, the fallout from which has approximately the same acidity as at Crête).

The dating of the Camp Century core cannot compare with that of the Crête core, although it has been dated by the  $\delta$  method to better than  $\pm 2\%$  through the interval<sup>10</sup> 2,000–10,000 yr BP. Further improvement of the time scale over the past 4,000 yr has been obtained by using the AD 1259 and 1783 reference horizons as fixed points and also using all presently available data on the annual layer thickness  $\lambda$ , which decreases from 19 cm in 2,000-yr-old ice to 2 cm in 10,000-yr-old ice due to plastic thinning of the annual layers as they sink towards greater depths<sup>10</sup>.

A continuous acidity profile (one acidity mean value for each 10-cm increment) has been measured along the Camp Century

Fig. 3 Acidity signals exceeding  $4 \mu\text{equiv. H}^+$  per kg ice in the past 10,000 yr, but for AD 44–552. Large eruptions have occurred most frequently in the earliest and in the latest millenium of the period (compare with ref. 30). Up to AD 43 the analyses were performed on the Camp Century ice core; since AD 553 on the Crête ice core.

ice core from a depth of 558 m of ice, corresponding to AD 43, to the bedrock. Very high acidity spikes were analysed back to 8,000 BC with a resolution higher than  $\lambda$  at the particular depths. For clarity Fig. 3 shows only the mean acidity of the most acid annual layer within each one of those signals that can be ascribed to a single violent eruption. This procedure probably reveals all the large, violent eruptions, whereas all the eruptions up to medium magnitude, as well as large long-lasting but less violent eruptions are deleted. For comparison, the Crête record in Fig. 1 has been treated in the same way and added to the top of Fig. 3. The approximate magnitudes of some of the eruptions in terms of acid-gas production are listed in Table 1, estimated by the same procedure as used on the Crête core.

The frequency of violent eruptions is clearly relatively low from 1500 to 7000 BC, in particular from 3500 to 5500 BC. Some of the most outstanding events are now discussed.

**50  $\pm$  30 BC:** The acid fallout lasted ~3 yr (compare with Fig. 4a) and must be due to one of the largest eruptions in the Northern Hemisphere since the last glaciation. There is no evidence of any great eruption in Iceland at this time. If Etna really had an eruption in the year of Caesar's death<sup>20</sup>, 44 BC, it could explain Virgil's statement<sup>21</sup> that "when Caesar died, the Sun felt pity for Rome, as it covered its beaming face by darkness, and the impious generation feared an eternal night". But, if the heavy fallout in Greenland were to be ascribed to Etna, the magnitude of the eruption and its impact on the Roman society would have been so great that there would undoubtedly be geological and historical evidence. A century later the Elder Plinius mentioned<sup>2</sup> the "feebleness of the Sun through nearly a year, when the dictator Caesar was killed", which suggests there was a widespread aerosol from an unusually large eruption somewhere else.

**210  $\pm$  30 or 260  $\pm$  30 BC:** Might reveal the Younger Laxar-lava (Iceland; Thorarinnsson, personal communication).

**1100  $\pm$  50 BC:** The greatest post-glacial eruption of Hekla (H3) has been radiocarbon dated at  $950 \pm 130$  BC (ref. 22), that is not significantly different from  $1100 \pm 50$  BC. The estimated total volume of freshly fallen tephra was  $12 \text{ km}^3$  (ref. 23), corresponding to some 30% of the material extruded by Laki (1783).

**1390  $\pm$  50 BC:** (Compare details in Fig. 4b). This is the only signal exceeding  $2.6 \mu\text{equiv. H}^+$   $\text{kg}^{-1}$  between 1100 and 2700 BC, and we therefore interpret it as being due to the large eruption of Thera (Santorini) in the Aegean Sea, which is generally agreed to have been of the same magnitude as that of Tambora (1815). The tephra production has recently been estimated at more than  $28 \text{ km}^3$  ( $13 \text{ km}^3$  of dense rock equivalent)<sup>24</sup>. This unusually large eruption has been radiocarbon dated at  $1720 \pm 50$  BC on the calibrated radiocarbon scale (ref. 25, and H. Tauber, personal communication). However, archaeological evidence from the excavation of the Minoan settlement near Akrotiri on Santorini strongly suggests<sup>26</sup> that the island was inhabited at least up to 1500 BC judging by Egyptian pottery style chronology; it was apparently abandoned shortly before the eruption, and in good order because no valuables have been found nor people killed by the heavy ash fall (10–40 m). The discrepancy between the datings may be partly explained if the organic material used for the radiocarbon dating were partly built up by radioactively dead  $\text{CO}_2$  exhausted from the volcano before the eruption (an effect which has been observed recently<sup>27</sup>). Our dating around 1400 BC supports Marinatos' theory<sup>28</sup> of a causal connection between the Thera eruption and the decline of the Minoan civilization centred on the island of Crete. The dating can be further improved to  $\pm 10$  yr, if and when a deep Central Greenland ice core becomes available.

**2700  $\pm$  70 BC:** Agrees with the radiocarbon dating  $2550 \pm 120$  BC of the Hekla eruption H4, which is estimated to have been almost as great as H3 (ref. 23).

**3250  $\pm$  80 BC:** This signal is difficult to reconcile with any known giant eruption, but the one at

**4400  $\pm$  100 BC:** Agrees with Mt Mazama, Oregon, the radio-

**Fig. 4** Unambiguous volcanic signals in Camp Century ice core increments spanning the AD 43–140 BC, and the 1300–1500 BC time intervals. *a*, The unusually large event at  $50 \pm 30$  BC may be the one that caused the optical phenomena in the atmosphere described at Julius Caesar's death 44 BC. *b*, The only high signal in the entire period (in fact between 1120 and 2690 BC) occurred at  $1388 \pm 50$  BC. With the only reservation that another high signal might be lost in the few per cent of missing core, the observed event can be identified with the large Thera eruption in the Aegean Sea that deeply influenced the ancient Minoan society.

carbon datings of which range from 4200 to 4600 BC<sup>29</sup>. The amount of freshly fallen ash is estimated at 30 km<sup>3</sup>.

**5400 ± 120 BC:** Agrees with the Hekla eruption H5, radio-carbon dated at  $5450 \pm 190$  BC<sup>22</sup>, and with the largest Thjórsá lava flow, dated by Thorarinsson at ~5500 BC.

None of the high signals before 6000 BC can be safely ascribed to any eruption known by us. Not less than seven great eruptions seem to have occurred between 7000 and 8000 BC. According to Thorarinsson (personal communication), at least some of these must be Icelandic shield volcanoes, such as Skjaldbreidur (15 km<sup>3</sup>; ~10,000 yr ago).

No unambiguous evidence of volcanic fallout has been found in the deep ice, which was deposited during the last glaciation, judging from very low  $\delta$  values in the complete  $\delta$  profile<sup>19</sup>. As the volcanic activity was hardly negligible in this period<sup>30</sup>, our measuring technique, at least in the present form, obviously cannot be applied to the Camp Century core before 8000 BC. One reason is the limited resolution power of the electrodes, but the main reason is that, disregarding the interstadials revealed by intermediate  $\delta$  values, the ice from the last glaciation is slightly alcalic, which makes the current between the electrodes nearly zero. In alcalic ice the chemical element content measured so far<sup>31</sup> is higher than in post-glacial time by factors of, for example, 1.5–3 for Na and SO<sub>4</sub><sup>2-</sup>; 2.5–11 for K, Mg, Si and Al; and 10–30 for Ca. The elevated sulphate values are probably just part of the generally increased impurity background, and measuring the volcanic contribution calls for very detailed sulphate analyses. The extremely high calcium values probably originate from CaCO<sub>3</sub> dust from the exposed continental shelves<sup>31</sup>, indicating an alcalic aerosol able to neutralize an acid aerosol that would otherwise cause acidities of up to 8 μequiv H<sup>+</sup> per kg ice.

In preglaciation ice, characterized by high  $\delta$  values, the chemical impurity concentrations and the acidity background come close to post-glacial values. There is some indication of periods of intense volcanism, but the resolution is too poor for further details.

## The climatic impact of volcanism

Volcanic aerosols influence the radiation balance in the atmosphere. The optical thickness  $\tau$  of an atmospheric aerosol is an index of the loss of radiation by scattering and absorption (the optical thickness of a layer is  $\tau$ , if the fraction  $\exp(-\tau)$  of radiation impinging perpendicularly on the layer is transmitted).  $\tau$  is an important parameter in radiation balance models for calculating the temperature effect of volcanic aerosols in the stratosphere. The optical properties of an assumed sulphuric acid aerosol have been estimated<sup>3</sup> using the measured global 'average' optical depths since 1882. It was thereby possible to calculate temperature changes ( $\Delta T$ ) close to those observed in the atmosphere after volcanic eruptions, including the Agung eruption 1963 that caused up to several degrees warming of the low latitude stratosphere<sup>32</sup> and a 0.4 °C cooling of the low-latitude troposphere<sup>33</sup>. However, an important drawback in these calculations is "that the sign and magnitude of  $\Delta T$  depends critically on the real and imaginary parts of the refractive indices of the added particles, their size distribution, and the surface albedo"<sup>3</sup>, which, of course, stresses the need for a direct comparison between volcanic activity and climatic changes before the instrumental epoch.

The Crête excess-acidity data given in Fig. 1 must be expected to be proportional to the volcanic contribution  $\Delta\tau$  to the optical depth in the high northern latitude atmosphere. As a first approximation we further assume that this  $\Delta\tau$  is just as relevant for comparison with climatic temperature changes as is the global averaged  $\Delta\tau$ . This is often implicitly assumed in model calculations, where the latitude-dependent back scattering has been averaged.

Figure 5e shows the Crête acidity profile in 50-yr averaged values. Note that periods of low volcanic activity have been marked in black. The maximum deviation from the overall mean is  $< 0.5 \mu\text{equiv H}^+ \text{ kg}^{-1}$  (measured on solid ice<sup>9</sup>), corresponding to only 0.03 and 0.05 deviation of pH measured on melted samples, assuming saturation with CO<sub>2</sub> in ambient air at 0° and

Fig. 5 Correlation between climatic temperature variations (curve *d*, composed of the three indirectly determined records *a* through *c*; warm periods are set out in black) and volcanic activity (curve *e*, showing an acidity profile along the Crête ice core; lower than normal volcanism corresponds to low acidities set out in black).

25 °C, respectively. This might be why 'remarkably stable' 50-yr mean pH values in meltwater from most of the Devon Island ice core<sup>34</sup> were interpreted to indicate that 'volcanic activity has not altered significantly' during the period 50–5300 yr BP.

To examine the possible influence of volcanic activity on climate we compare below the Crête acidity record with some absolute-dated climatic records of proxy data reaching far beyond the period of direct temperature observations. As the ice acidity data are more or less representative of aerosol conditions in the Northern Hemisphere in general, they ought to be compared with temperatures of similar general validity, rather than data representative of regional climatic conditions, for example, central England temperature estimates (Fig. 5a; ref. 35); or white Mountains, California, tree ring widths (Fig. 5b; ref. 36); or the long-term  $\delta$ -variation in Greenland ice sheet precipitation (Fig. 5c; combination of four normalized  $\delta$ -profiles back to AD 1250; two back to AD 550; ref. 37). But, if

these three climatic curves are combined after normalization, the resulting record (Fig. 5d) may be a first approximation to the Northern Hemisphere temperature index needed for making a useful comparison with past volcanic activity. Unfortunately, most other long-term climatic records do not meet the strict requirement to the dating accuracy needed in this context.

The Northern Hemisphere temperature index in Fig. 5d does not have a temperature scale, of course. Most of its trends are recognized, more or less, in each of its components—the warm first half of the twentieth century; the cooler nineteenth century; the relatively warm eighteenth century; the 'Little Ice Age' AD 1350–1700 with a minor 'interstadial' AD 1500–1550 (or AD 1350–1900 with 'interstadials' 1500–1550 and 1700–1800), and the mediaeval warmth AD 1000–1300, although the latter seems to have occurred earlier in Greenland.

Many of the above-mentioned features can be recognized in the Crête acidity curve (Fig. 5e), warmth generally occurring in periods of lower than average volcanic activity. The correlation coefficient between curves 5d and 5e is  $R = -0.52$  ( $P > 95\%$  for 12 d.f.). The curves exhibit a few clear discrepancies, particularly between the data in the AD 850–900 interval. Such occasional discrepancies are not surprising in view of the increasing uncertainty of the temperature index backward in time (for example Lamb gives only one mean temperature estimate for the entire period AD 800–1000). Furthermore, curve *e* is hardly the best obtainable representative of volcanic activity. It could, for example, be improved by replacing the simple acidity measurements by a more differentiated chemical investigation.

The significant correlation between curves *d* and *e* (Fig. 5) indicates that persistent volcanic activity north of 20° S is probably an important, but not necessarily the only, cause of climatic fluctuations of up to several hundred years duration at mid- and high-latitudes. If true, a solution of the extremely important and difficult problem of predicting climatic changes by atmospheric model calculations implies a scarcely easier prediction of volcanic activity.

*A priori*, the acid aerosol load at low latitudes cannot be expected to vary in parallel with curve *e* (Fig. 5) nor, therefore, with the Northern Hemisphere temperature index (curve *d* Fig. 5). This suggests that future climate models should account for the latitudinal variation of the optical depth of volcanic aerosols, rather than using a global average.

A similar treatment of the Camp Century data has been attempted with some success and will be reported elsewhere.

We thank Professor Chester C. Langway, for permission to analyse the Camp Century ice core, and Dr S. Thorarinsson for valuable help. The Danish Commission for Scientific Investigations in Greenland funded the study.

*Note added in proof:* In a new ice core from South Greenland, a strong acidity signal was found and preliminarily dated at AD 540 ± 10. This might be the Yukon eruption mentioned above. If so, the global acid fall out was of the order of 70 million tons.

# Nucleotide sequence of cDNA coding for Semliki Forest virus membrane glycoproteins

Henrik Garoff, Anne-Marie Frischauf, Kai Simons, Hans Lehrach & Hajo Delius

European Molecular Biology Laboratory, Postfach 102209, 6900 Heidelberg, FRG

*The genes coding for the three membrane polypeptides of Semliki Forest virus have been sequenced and the primary structures of the proteins deduced. The amino acid sequence gives further insight into how the transmembrane structure of the three-chain virus membrane glycoprotein is generated in the infected cell.*

MANY enveloped animal viruses acquire their membranes at the host cell surface<sup>1</sup>. The virus membranes are highly differentiated plasma membranes which can be studied as models for plasma membrane assembly<sup>2-7</sup>. Semliki Forest virus (SFV) consists of a nucleocapsid surrounded by a lipid envelope. The virus membrane is studded with glycoprotein spikes which are essential for virus attachment and penetration into host cells<sup>8</sup>. Each spike glycoprotein contains three different glycopolypeptides: E1 (molecular weight ( $M_r$ ) 49,000), E2 ( $M_r$  52,000) and E3 ( $M_r$  10,000)<sup>9,10</sup>. E3 is external to the lipid bilayer whereas E1 and E2 are attached by short hydrophobic polypeptide segments to the membrane. E2 spans the membrane, having about 30 amino acid residues of its carboxy terminus internal to the bilayer<sup>11</sup>. In infected cells, two species of virus mRNA are found—the 42S RNA, the virus genome and the 26S RNA<sup>12</sup>. The latter RNA molecule is homologous to the 3' end of the 42S RNA<sup>13</sup> and serves as mRNA not only for the E1, E2 and E3 polypeptides but also for the capsid protein of the virus nucleocapsid. All four polypeptides are translated from the 26S RNA using a single initiation site in the order: capsid, p62 and E1<sup>14,15</sup>. The p62 polypeptide is the precursor of E3 and E2<sup>9</sup>. The capsid protein is cleaved from the nascent chain immediately after it is completed and is left in the cytoplasm<sup>16</sup>. The amino-terminal end of p62 then directs the polysomes to the endoplasmic reticulum where the synthesis of the glycoproteins continues concomitantly with membrane translocation and glycosylation<sup>16</sup>. The newly synthesized p62 and E1 glycopolypeptides form a complex which migrates through the intracellular membrane system to the plasma membrane, where the p62 protein is cleaved to form E2 and E3<sup>17</sup>.

We now report the nucleotide sequence of the cloned cDNA made from the 26S RNA, which codes for the SFV membrane proteins. The amino acid sequence suggests how the glycoproteins are attached to the membrane and provides further insight into how one mRNA directs the synthesis of four polypeptides destined for two different locations of the cell.

## Cloning of membrane protein genes

The viral genome (42S RNA) obtained from virus particles and 26S RNA isolated from infected cells were used as templates for cDNA synthesis from the 3' end of the RNA molecules<sup>18</sup>. The first strand was made with reverse transcriptase and the second with DNA polymerase<sup>19</sup>. The double-stranded cDNA was inserted into the vector pBR322 at the *Pst*I site using the oligo(dG-dC) tailing procedure described by Röwekamp and Firtel<sup>20</sup>. The hybrid plasmid was then used to transform *Escherichia coli*  $\chi$ 1776 (ref. 21). Tetracycline-resistant colonies, which hybridized strongly to <sup>32</sup>P-labelled cDNA made from 42S RNA<sup>22</sup>, were screened to determine the length of the insert molecule<sup>23</sup>.

Several clones containing hybrid plasmids with inserts larger than 1 kilobase were found. Electron microscopic analysis of hybrids<sup>18,24,25</sup> formed between the 42S RNA and DNA inserts showed that three hybrid plasmid clones—pBR SFV 1, 2 and

3—covered the entire 26S RNA region with the exception of about 150 bases from the 3' end. The insert molecule in pBR SFV 1 contained about 2.0 kilobases from the 3' end of the 26S RNA. pBR SFV 2 contained some 2.25 kilobases from the middle region of the 26S RNA. It overlapped by about 1.35 kilobases with the insert of pBR SFV 1. The insert of pBR SFV 3, made from the 42S RNA, contained 1.6 kilobases and was some 250 bases longer than the 5' end of the 26S RNA. It had an overlap of 300 bases with the pBR SFV 2 insert. All inserts were mapped with restriction endonucleases using the technique described by Smith and Birnstiel<sup>26</sup>. Figure 1 shows agarose gel analyses of the partial digestion products of pBR SFV 1 and pBR SFV 2. The restriction endonuclease mapping of pBR SFV 3, which covers the entire gene of the capsid protein, is presented elsewhere<sup>18</sup>. Figure 2 shows the restriction map of the region coding for the membrane proteins. The capsid protein gene ends some 100 bases away from the *Xho*I site in the direction towards the 5' end<sup>18</sup>.

## Nucleotide sequencing

DNA fragments for sequencing were prepared using two different approaches. The first one was based on the restriction map (Fig. 2). The DNA was cleaved using a suitable restriction endonuclease. After labelling either the 3' or the 5' ends of the DNA fragments, these were cleaved a second time to produce pieces of DNA that had only one labelled end<sup>27</sup>. The various fragments were isolated and sequenced as described in Fig. 2 legend. In the second procedure we deleted *in vitro* the DNA region of the vector between the *Eco*RI site and the *Pst*I site (748 base pairs)? together with different-sized portions of the insert molecule (see Fig. 2 legend). When these molecules were recloned, it was possible to sequence directly from the *Eco*RI site of the subcloned plasmid into the insert region (see Fig. 2 legend). This sequencing procedure will be presented in detail elsewhere (A.-M. F., H.G. and H.L., in preparation). The sequenced stretches of DNA are indicated by the arrows in Fig. 2. The sequences were overlapped using a computer program (H. L., unpublished). Figure 3 shows the nucleotide sequence of the region coding for the membrane proteins. The C at the 3' end of the sequence corresponds to the nucleotide before the poly(A) tail in the 26S RNA<sup>30</sup>. We have included the nucleotide sequence on the 5' side of the *Xho*I site that codes for the carboxy terminus of the capsid protein<sup>18</sup>. The complete sequence of the capsid protein will be published elsewhere<sup>18</sup>.

## Amino acid sequence

Translation of the nucleotide sequence into amino acids using the same reading frame that was earlier used to deduce the primary structure of the capsid protein resulted in a continuous sequence of amino acids (Fig. 3). Reading in the two other frames was interrupted by 40 and 45 nonsense codons, respectively. The coding region of the 26S RNA thus starts with the amino terminus of the capsid protein and terminates 3,759.

**Fig. 1** Analyses of partial digestion products of end-labelled pBR SFV 1 (a) and pBR SFV 2 (b) by electrophoresis on 1.4% agarose gels (20 cm × 40 cm, 1.5-mm thick). pBR SFV 1 (10 µg) was linearized with *EcoRI* and the same amount of pBR SFV 2 was cleaved with *Clal*. The 5' ends were dephosphorylated and labelled using polynucleotide kinase and  $^{32}\text{P}$ -ATP (ref. 27). After a second cleavage with *Bam*HI, both DNA samples were subjected to partial digestions with the restriction endonucleases indicated at the top of the figure. The exact incubation conditions as well as the electrophoresis procedure, the drying of the gel and the autoradiography are described elsewhere<sup>18</sup>. Fragments generated by cleavages within the insert of pBR SFV 1 are distributed between the two arrows in a. Cleavage sites in the insert molecule of pBR SFV 2 are shown by the bands between the arrows in b. Some of the digestions of pBR SFV 2 were either too complete or incomplete. These are repeated in a second experiment (right part of b). Here the smallest (748 base pairs) and the largest *Pst*I fragments indicate the limits of the fragments derived from the insert. The partial digestion products of pBR322 that were end labelled in the *EcoRI* site were used as standards<sup>28</sup>.

nucleotides later when the first stop codon (TAA in Fig. 3) is reached. The regions coding for the E3, E2 and E1 polypeptides were localized in this sequence using data available from amino-terminal amino acid sequencing (refs 31, 32 and H. Garoff, H. Riedel and H. Lehrach, in preparation) and carboxypeptidase digestions of the isolated polypeptides<sup>33</sup>.

The amino terminus of the isolated E3 polypeptide contains a methionine residue in position 8 and leucine residues in positions 4 and 11 (W. Welch and B. Sefton, personal communication). This amino acid sequence is found immediately after the region coding for the capsid protein (Fig. 3). Bonatti

and Blobel have reported a highly homologous sequence at the amino terminus of the precursor for the E3 and E2 polypeptides from the closely related Sindbis virus<sup>32</sup>. The carboxy-terminal sequence His-Arg, determined from the isolated E3 polypeptide<sup>33</sup>, is found 64 amino acid residues from the carboxy terminus of the capsid protein preceding the known amino terminus of E2 (Ser-Val-Ser-Gln-His-Phe-)<sup>31</sup>. As there are two arginine residues before the amino terminus of E2, the last one might be excised by a host protease during cleavage of the p62 polypeptide to E3 and E2 (see below). The amino-terminal sequence determined from the isolated E1 polypeptide

**Fig. 2** Restriction endonuclease map of the SFV membrane protein region in pBR-SFV 1-3. Thick arrows indicate stretches of DNA where both strands have been sequenced. Thin arrows indicate either 3' end or 5' end sequences. There are no sequence data that overlap the *Xho*I site. However, the corresponding region in the E3 protein is covered with partial amino acid sequence data from a cyanogen bromide peptide (H. Garoff, H. Riedel and H. Lehrach, in preparation). The arrows inside the restriction map represent sequences obtained from isolated DNA fragments and those below the map represent sequences obtained using the subcloning approach. The preparation of subcloned plasmids for sequencing from pBR-SFV 1 and 2 will be described elsewhere (A.M.F., H.G. and H.L., in preparation). The steps were as follows: (1) Random linearization of the hybrid plasmid with DNase I. (2) Ligation of *Eco*RI linkers to the ends. (3) Cleavage of the linkers and the vector with *Eco*RI. (4) Separation of DNA molecules by electrophoresis in agarose gels and elution of such molecules which were expected to have deletions extending from the *Eco*RI site of the vector to different positions in the insert. (5) Ligation of the cleaved *Eco*RI octamer at the end of the insert with the cleaved *Eco*RI site of the vector. (6) Transformation and isolation of subcloned plasmids. In these plasmids the regenerated *Eco*RI site is adjacent to different regions of the original insert. The subcloned plasmids were prepared for sequencing using the simple approach: cut with *Eco*RI, label and recut with *Cl*AI. As *Cl*AI cleaves only 20 bases from the *Eco*RI site, the plasmid preparation could be sequenced without further purification steps. Fragments were isolated from pBR-SFV 3 as follows: (1) Cut with *Xho*I, label, recut with *Cl*AI which cleaves in the vector, isolate 4,106-base pair fragment. (2) Cut with *Ava*I, label, recut with *Eco*RI, isolate 408-base pair fragment. (3) Cut with *Eco*RI, label, recut with *Xho*I, isolate 408-base pair fragment. (4) Cut with *Hind*III, label, (i) recut with *Hae*III (vector), isolate 422-base pair fragment, (ii) isolate 697-base pair fragment, recut with *Xho*I, isolate 224-base pair fragment. Fragments from pBR-SFV 2: (1) Cut with *Taq*I, label, (i) recut with *Hind*III (vector), isolate 701-base pair fragment; (ii) recut with *Hae*III, isolate 546-base pair fragment. (2) Cut with *Ava*I, label, recut with *Pst*I, isolate 620- and 488-base pair fragments. (3) Cut with *Hpa*II, label, isolate 345-base pair fragment, recut with *Hae*III, isolate 307-base pair fragment. (4) Cut with *Hae*III, label, isolate 437-base pair fragment, recut with *Hpa*II, isolate 277- and 160-base pair fragments. (5) Cut with *Ava*I, label, recut with *Pst*I, isolate 1,612-base pair fragment. Fragments from pBR-SFV 1: (1) Cut with *Hpa*II, label, (i) isolate 1,036-base pair fragment, recut with *Hind*III, isolate 648- and 388-base pair fragments, (ii) recut with *Hind*III, isolate 830-base pair fragment. (2) Cut with *Pst*I, label, recut with *Hind*III, isolate 521-base pair fragment. (3) Cut with *Ava*I, label, recut with *Hae*III, isolate 1,789- and 950-base pair fragments. (4) Cut with *Taq*I, label, (i) isolate 865-base pair fragment, recut with *Hpa*II, isolate 369-base pair fragment, (ii) isolate 405-base pair fragment, recut with *Hind*III, isolate 176- and 229-base pair fragments, (iii) isolate 354-base pair fragment, recut with *Hpa*II, isolate 159- and 195-base pair fragments, (iv) isolate 1,768-base pair fragment, either recut with *Hind*III, isolate 635-base pair fragment, or recut with *Hae*III, isolate 86-base pair fragment. (5) Cut with *Hind*III, label, (i) recut with *Hpa*II, isolate 648-base pair fragment, (ii) recut with *Hind*III, isolate 1,218-base pair fragment. (6) Cut with *Hind*III, label, (i) recut with *Eco*RI, isolate 2,708-base pair fragment, (ii) recut with *Bam*HI (vector), isolate 3,320-base pair fragment. All fragments were isolated by electrophoresis in agarose gels and subsequent electroelution into hydroxyapatite<sup>28</sup>. DNA sequencing was done using the base-specific cleavage reactions described by Maxam and Gilbert<sup>27</sup>. We used five reactions: G, G+A, C+T, C, C+A. kb, Kilobases.

(Tyr-Glu-His-Ser-Thr-Val)<sup>31</sup> is found 482 amino acids from the amino terminus of E2. However, the carboxy terminus of E2, which has been shown to be His-Ala (ref. 33), is not present immediately before the amino terminus of E1, but 60 amino acid residues earlier. This leaves a 60-residue peptide between the regions coding for E2 and E1. Recently, Welch and Sefton have found a peptide with a  $M_r$  of 6,000 (6K) in extracts of cells infected with SFV<sup>34</sup>. The 6K peptide was coded for by the 26S RNA, but was not found in the virus particle. Partial amino acid sequencing showed that the 6K peptide has a methionine at position 7 and leucines at positions 10 and 17. (W. J. Welch and B. M. Sefton, personal communication), in agreement with the sequence of the 60-amino acid residue segment beginning after the carboxy terminus of E2. The E1 polypeptide terminates at the TAA-438 amino acids after its amino terminus. Carboxypeptidase experiments have shown that the E1 polypeptide terminates with an arginine residue<sup>35</sup>, in agreement with the sequence shown in Fig. 3.

The deduced amino acid sequences of the polypeptides have been fully confirmed by partial amino-terminal amino acid sequencing of fragments obtained by cyanogen bromide cleavage of the isolated E1, E2 and E3 polypeptides (H. Garoff, H. Riedel and H. Lehrach, in preparation). The calculated amino acid compositions of the E3, E2 and E1 polypeptides are in good agreement with those obtained experimentally<sup>9</sup>.

### Sites of glycosylation

All three membrane polypeptides contain carbohydrate units linked to asparagines<sup>35,36</sup>. Carbohydrate units in glycoproteins are known to appear either in Asn-X-Ser or in Asn-X-Thr sequences, the presence of these sequences being a necessary

but not a sufficient condition for glycosylation<sup>37</sup>. Two such sequences are found in the E3 protein (Asn 13-Ala-Thr and Asn 60-Gly-Thr) (Fig. 3). The single oligosaccharide unit known to be present in E3 can therefore be attached to either of these asparagine residues. The E2 protein contains two possible glycosylation sites (Asn 200-Cys-Thr and Asn 262-Ile-Thr), both of which must be glycosylated as this protein has two oligosaccharide units. The single carbohydrate unit of E1 must be attached to Asn 141-Gln-Thr because this is the only potential glycosylation site in the E1 protein.

When the  $M_s$  of the protein (from the sequence) and the carbohydrate parts (from previous gel filtration data) are summed for E1 (47,386+3,400), E2 (46,755+5,100) and E3<sup>35</sup> (7,369+4,000), there is good agreement with the apparent  $M_s$  determined for the proteins by SDS gel electrophoresis<sup>9</sup>.

### Location of the transmembrane segments

We used the criteria devised by Segrest and Feldman<sup>38</sup> to search for hydrophobic sequences in the SFV proteins. Peptides longer than 10 amino acids and lacking charged residues (lysine, arginine, glutamic acid and aspartic acid) were identified and plotted according to their hydrophobicity per unit length. Most of the sequences that were found fall within the triangular area where apolar peptides of globular proteins map. Four peptides mapped in the region to the right of the triangle where the transmembrane domain of glycoprotein<sup>39</sup> and the hydrophobic domains of the haemagglutinins of Influenza virus<sup>40,41</sup> are located (Fig. 4). Three of these peptides were in the SFV membrane proteins, the fourth was in the non-structural 6K peptide. Peptide 24 from E1 (Fig. 4) and peptide 10 from E2 are

[illegible]

**Fig. 3** The nucleotide sequence of the membrane protein genes. The deduced amino acid sequences of the membrane proteins are shown below. The amino acid residues are numbered from the amino terminus of each polypeptide. The positions are shown in the parentheses to the right. Membrane-spanning segments are underlined and potential glycosylation sites are marked (●).

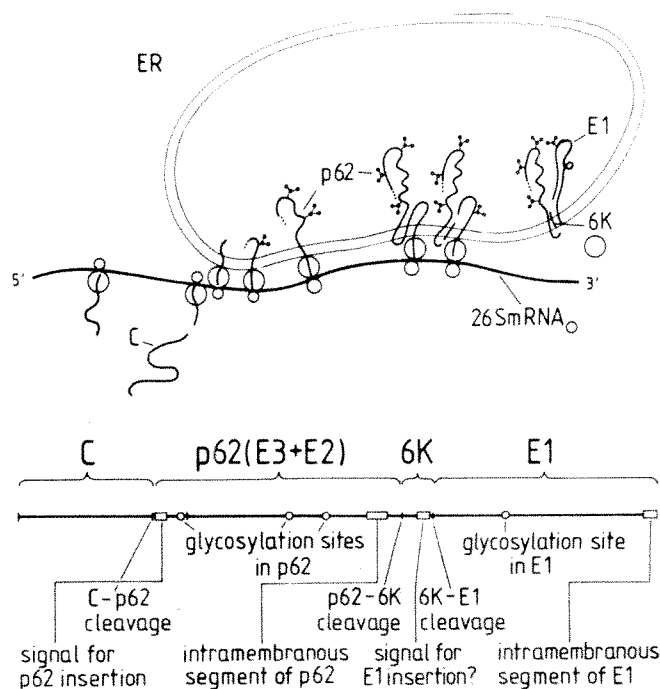

long enough to span the lipid bilayer in the form of an  $\alpha$ -helix<sup>38</sup>. These peptides are located in the carboxy-terminal regions of E1 and E2, respectively, where the hydrophobic domains of E1 and E2 have previously been mapped<sup>11</sup>. The presumptive transmembrane domain of E2 is located between Lys 346 and Arg 392, 31 amino acids away from the carboxy terminus, in complete agreement with our previous biochemical data<sup>11</sup>. The transmembrane domain of E2 is rather long, as defined in the diagram shown in Fig. 4. However, scrutiny of the amino acid sequence shows that it contains two histidines at positions 348 and 352 and two glutamines at positions 353 and 356. These may be located in the external domain outside the bilayer because these amino acids have not been found in the other known transmembrane domains. Furthermore, if we assume an  $\alpha$ -helix for the membrane-spanning segment, the proline residue at position 363 would also be excluded from the bilayer, leaving 28 residues in the transmembrane domain. However, we cannot exclude the possibility that more of the segment is in the bilayer.

The hydrophobic domain of E1 is 24 residues long, only two amino acid residues away from the carboxy terminus. There is no evidence from previous studies that this domain spans the membrane, but the methods we previously used to demonstrate spanning would not have detected the very short segment of two arginine residues<sup>11,42</sup>. Examination of the known and presumptive transmembrane domains of cell surface<sup>39,43,44</sup> and virus glycoproteins<sup>40,41</sup> (including E2) show that they are all characterized by hydrophobic segments at least 23 amino acid residues long (lacking Lys, Arg, Asp, Glu, Gln, Asn, His and Pro residues) followed by one or several closely spaced basic amino acids on their carboxy-terminal side marking the start of the cytoplasmic domain. The hydrophobic domain of the E1 polypeptide fulfills these criteria. Its cytoplasmic domain would thus be only two arginine residues long.

**Fig. 4** Hydrophobicity diagram of apolar sequences in SFV proteins. The hydrophobicity of apolar peptides containing 10 or more amino acids was calculated as described by Segrest and Feldman<sup>38</sup> and these values were plotted against the lengths of the peptides. The upper part of the figure shows the location of the apolar sequences on the polypeptides translated from the 26S RNA. Symbols:  $\times$ , apolar peptides from SFV proteins; these are numbered according to their location.  $\circ$ , Membrane-spanning peptides from glycoporin (marked MN)<sup>39</sup>, the haemagglutinin protein from fowl plague virus (FPV)<sup>40</sup> and influenza virus A strain Victoria<sup>41</sup>.  $\Delta$ , Apolar segments of amino-terminal extensions (signal peptides) of various secreted proteins (see ref. 60).

The third hydrophobic peptide mapping to the right of the triangle in Fig. 4 is located between Lys 79 and Asp 97 in the external hydrophilic domain of E1. This region is amino terminal to the presumptive attachment site for the oligosaccharide side chain. It is 16 amino acids long and is interrupted by a proline residue, much in the same way as the hydrophobic domain of cytochrome  $b_5$  (ref. 45). This region could be involved in the membrane fusion activity displayed by the SFV spike glycoprotein during virus entry into the host cell through the lysosomes<sup>46</sup>. At  $\leq$  pH 6, the membrane of SFV fuses with cholesterol-containing phospholipid bilayers<sup>47</sup>. One could envisage that the low pH induces a conformational change in the E1 polypeptide, exposing this hydrophobic peptide which could then insert into a neighbouring lipid bilayer to initiate fusion of the apposed membranes. The amino-terminal region of the Sendai virus fusion protein, thought to be involved in membrane fusion, is also relatively hydrophobic<sup>48</sup>.

**Fig. 5** Scheme for the assembly of SFV membrane glycoprotein into the membrane of the endoplasmic reticulum. C is the capsid protein which remains in the cytoplasm.

## Proteolytic cleavages involved in synthesis of SFV proteins

The nucleotide sequence of the DNA, copied from the 26S RNA, has confirmed the order determined previously for the genes coding for the SFV proteins<sup>11,14</sup>. The coding regions are contiguous except between E2 and E1, where an additional gene segment was found coding for 60 amino acids, the 6K peptide described by Welch and Sefton<sup>34</sup>. This would imply that at least four proteolytic cleavages are needed to generate the four structural polypeptides of the virus. Previous studies have shown that the capsid protein is cleaved from the nascent chain as soon as translation of the protein is completed<sup>16</sup>. This cleavage is mediated either by the capsid protein itself<sup>49</sup> or by a ribosomal protease<sup>50</sup>, as it has been observed *in vitro* in all eukaryotic protein-translation systems tested. The excision of the 6K peptide also occurs on the nascent chain and may involve host proteases. The fourth cleavage which generates the E3 and E2 polypeptides from the p62 protein occurs about 30 min after synthesis<sup>17</sup>. The cleavage is blocked by antibodies against the SFV spike glycoproteins added to the infected cells, and prob-

ably occurs at the plasma membrane<sup>17,51</sup>. The cleavage site is next to an arginine pair located before the amino terminus of E1. Many prohormones and proproteins are processed to their final forms through specific cleavages at sites bearing pairs of basic amino acid residues (lysine and arginine). This is the case for proinsulin<sup>52</sup>, progastrin<sup>53</sup>, proglucagon<sup>54</sup>, proalbumin<sup>55</sup>, parathyroid hormone<sup>56</sup> and the common precursor for melanotropins, corticotropin, lipotropin and endorphins<sup>57</sup>. These cleavages which probably involve a combined trypsin-like and carboxypeptidase B-like specificity occur late in secretion, shortly before extracellular release. The haemagglutinin of fowl plague virus is also split late during intracellular transport or at the plasma membrane by a host protease into two polypeptide chains by two cleavages involving the excision of a -Lys-Arg-Glu-Lys-Arg- connecting peptide<sup>40</sup>. It is tempting to speculate that the secreted proproteins and the virus membrane glycoproteins are processed by the same family of host proteases, part of the post-Golgi pathway to the cell surface. This would mean that the cleavage of the p62 polypeptides begins before their appearance on the cell surface.

### Assembly of SFV membrane proteins

Previous studies indicate that the p62 and the E1 polypeptides are transferred across the membrane of the endoplasmic reticulum as they are being synthesized<sup>16,32</sup>. Both polypeptide chains seem to have their own independent signal peptides for membrane insertion<sup>16,58,59</sup>. Membrane insertion and transfer of the p62 polypeptide occur *in vitro* only if microsomal vesicles are present in the translation assay before about 100 amino acids from the amino terminus of the p62 polypeptide have been made<sup>16</sup>. This region must therefore contain a functional signal peptide. There seems to be no significant homology in the primary structures of the different signal sequences so far known<sup>16,60</sup>. The only common feature is a central core of at least nine predominantly hydrophobic amino acids uninterrupted by charged amino acids<sup>61</sup>. This criterion is fulfilled by the amino-terminal region of the p62 protein (Fig. 3). The hydrophobicity of this peptide (no. 5 in Fig. 4) is low but not lower than that of other signal peptides (Fig. 4). An unusual observation is that the signal peptide of the p62 polypeptide is not removed during translation (ref. 32 and W. Welch and B. Sefton, personal communication). It is completely translocated through the membrane with the rest of the external p62 domain of the protein.

The evidence suggesting that the E1 polypeptide has its own independent signal peptide is based on observations using a temperature-sensitive mutant of SFV. Kääriäinen and co-workers have found a mutant of SFV in which the cleavage between the capsid and the p62 polypeptides is blocked at the nonpermissive temperature<sup>39</sup>. Although the p62 polypeptide is not inserted into the membrane of the endoplasmic reticulum in these conditions, the E1 polypeptide seems to be correctly translocated. Judging from the *M<sub>s</sub>* of the E1 polypeptide and the uncleaved capsid-p62 polypeptide, the 6K peptide seems also to be normally excised. It is not possible to define the exact location of the signal peptide for E1 from the amino acid sequence of this region (Figs 3, 4), but one possibility is that it is in the 6K peptide preceding the amino terminus of E1. In this case, polypeptide E1 would be released from the 6K peptide, presumably by a signal peptidase cleavage.

A scheme for the assembly of the SFV spike glycoprotein into the membrane of the endoplasmic reticulum is depicted in Fig. 5. The signal peptide of the p62 polypeptide mediates insertion into the membrane soon after capsid protein cleavage. Translocation of the growing chain continues until the carboxy-terminal transmembrane domain stops transfer of the polypeptide. The ribosome would either be detached from the membrane at this stage or remain bound to the membrane. When the signal peptide for E1 emerges from the ribosome, renewed membrane insertion and transfer would take place. We do not know exactly when and on what side of the membrane the cleavage releasing the 6K peptide occurs during translation. It would be helpful to know the location of the 6K peptide with respect to the membrane after excision. Translocation of the E1 polypeptide is not complete when the nonsense codon in the 26S RNA terminates translation but the transmembrane domain of E1 must be pulled into the membrane either by the spontaneous folding of the external glycosylated domain in the lumen of the endoplasmic reticulum or by the postulated translocation machinery in the membrane<sup>7</sup>. The cluster of basic amino residues on the carboxy-terminal side of the membrane-spanning segments may be needed to fix the polypeptides into the membrane.

We thank Evelyn Kiko and Hilkka Virta for technical assistance, Annie Biais for typing the manuscript, N. Kalkkinen, L. Kääriäinen, B. Sefton, J. Strauss for permission to use unpublished data, and A. Helenius, K. Matlin and G. Warren for helpful criticism. This work has been done in accordance with the German guidelines for recombinant DNA research.

## Stellar perturbations of the cometary cloud

Paul R. Weissman

Jet Propulsion Laboratory, Earth and Space Sciences Division,  
Pasadena, California 91103

The existence of a cloud of  $\sim 2 \times 10^{11}$  comets surrounding the Solar System and extending out to interstellar distances has been suggested by Oort<sup>1</sup> based on the observed distribution of inverse semi-major axes of the long-period comets. Simple statistical arguments can be used to update the current understanding of how stellar perturbations act on the Oort cloud, and to infer some of the cloud properties. Using such an approach it is shown here that the cloud radius is  $\sim 10^5$  AU, the mean 'thermal' velocity in the cloud is  $\sim 110$  m s<sup>-1</sup>, and the resulting perihelion distribution in the planetary region is uniform with  $q$ . Stars passing through the Oort cloud over the history of the Solar System have ejected at least 9% of the initial population, and have randomized the orbits of the remaining comets so as to leave little record of their initial state.

Dynamical studies using analytical<sup>2</sup>, statistical<sup>3</sup>, and Monte Carlo<sup>4</sup> techniques have shown that the cometary cloud hypothesis can explain the observed distribution of cometary orbits. While these studies have tended to emphasize the orbital evolution of the long-period comets once they enter the planetary region from the cloud, relatively little attention has been given to the dynamics of comets in the cloud, controlled principally by perturbations from passing stars. Previous studies of the stellar perturbation problem<sup>1,5-9</sup> have demonstrated that no simple, complete solution exists.

The general method of treating the problem is to assume the comet is stationary in space relative to the Sun and that stars move by at high velocity along straight line paths. This is a good approximation because comets in the Oort cloud are moving at speeds of the order of 1–100 m s<sup>-1</sup> while the entire Solar System is moving through the local group of stars at a velocity of 20 km s<sup>-1</sup>. The Sun's gravity perturbs the passing star but the deflection from a straight line is negligible: 0.12 degrees for a star passing 0.01 pc (2,063 AU) away at a velocity of 20 km s<sup>-1</sup>. The velocity change imparted to the comet by the passing star is

$$\Delta V = 2GM_s/RV_s \quad (1)$$

where  $G$  is the gravitational constant,  $M_s$  the mass of the star,  $R$  the impact parameter, and  $V_s$  the velocity of the passing star. The velocity impulse is directed towards the point at which the star makes its closest approach to the comet. For a typical  $1 M_\odot$  star passing at a distance of 1 pc and a velocity of 20 km s<sup>-1</sup> the velocity impulse  $\Delta V = 43$  cm s<sup>-1</sup>.

The Sun receives a similar impulse from the passing star though typically different in magnitude and direction. It is the net difference between the velocity impulse on the comet and the impulse on the Sun that determines the perturbation of the comet's orbit relative to the Sun. Previous studies have pointed out the importance of close stellar encounters where the comet-star distance is comparable with or less than the comet-Sun distance. The velocity changes from distant encounters are small in magnitude and tend to impart nearly the same impulse to the Sun and the comet, yielding little net effect. Close encounters, however, show much greater variation in both magnitude and direction of the velocity impulse on the comet relative to the Sun, and thus are dominant in determining the total perturbation on the comets, even though they are less frequent than the distant encounters.

The frequency of encounters between the Solar System and passing stars can be found by considering the volume of space swept out by the Solar System in a time  $T$

$$N = \pi R^2 VT \rho_s \quad (2)$$

where  $N$  is the number of encounters,  $V$  is the velocity of the Sun relative to the local group of stars,  $\rho_s$  is the local density of stars, and  $R$  is the radius of the Solar System cross-section to be considered. Taking  $V = 20$  km s<sup>-1</sup> and  $\rho_s = 0.08$  pc<sup>-3</sup> (from ref. 10) then

$$N = 5.1 \times 10^{-6} R^2 T \quad (3)$$

where  $R$  is in parsecs and  $T$  in years. For  $R = 1$  pc there is on the average one stellar encounter every  $2.0 \times 10^5$  yr or 5.1 encounters per Myr. If these parameters have been constant over the history of the Solar System then the cometary cloud has experienced  $2.3 \times 10^4$  stellar encounters at a distance of 1 pc or less in that time.

The mean energy perturbation caused by the passing stars can be found by integrating over concentric shells around the comet in space, with the number of stars passing at any distance  $R$  proportional to the volume of the shell at that distance.

$$\overline{\Delta V^2} = \int_{R_1}^{R_2} (\Delta V)^2 4\pi R^2 dR / \int_{R_1}^{R_2} 4\pi R^2 dR \quad (4)$$

Substituting for  $\Delta V$  in equation (1) and performing the integration gives

$$\overline{\Delta V^2} = 12 (GM/V)^2 (R_2 - R_1) / (R_2^3 - R_1^3) \quad (5)$$

The lower limit of the integration can be taken to be that distance at which a single encounter will eject a comet from the cloud. At  $5 \times 10^4$  AU from the Sun the escape velocity,  $V_e = 188$  m s<sup>-1</sup> and the impact parameter  $R_1 = 472$  AU for a  $1 M_\odot$  star passing at 20 km s<sup>-1</sup>; for  $10^5$  AU from the Sun  $V_e = 133$  m s<sup>-1</sup> and  $R_1 = 667$  AU. For the upper limit it has already been stated that  $R_2$  must be of the order of the dimensions of the cometary cloud or larger:  $\geq 10^5$  AU. Thus  $R_2 \gg R_1$  and the expression above can be simplified to

$$\overline{\Delta V^2} \approx 12 (GM/VR)^2 \quad (6)$$

where  $R$  is now equal to  $R_2$ , the upper limit of the Solar System radius of cross-section being considered. Again taking  $V = 20$  km s<sup>-1</sup> and assuming a  $1 M_\odot$  stars gives

$$\overline{\Delta V^2} = 0.55/R^2 \quad (\text{m s}^{-1})^2 \quad (7)$$

where  $R$  is in parsecs.

Fig. 1 Velocity phase space normal to a comet's radius vector showing relationship between initial aphelion velocity  $V_{\text{aph}}$ , tangential perturbation  $\Delta V_t$ , and new velocity  $V_{\text{new}}$ . Comets falling within the  $1.88$  m s<sup>-1</sup> circle around the origin will have perihelia  $\leq 5$  AU. An aphelion distance of  $5 \times 10^4$  AU is assumed.

The total r.m.s. velocity perturbation in any period of time is then given by the square root of the number of stellar passages within distance  $R$  times the mean energy perturbation

$$\Delta V_{r.m.s.} = (N \cdot \overline{\Delta V^2})^{1/2} = 1.7 \times 10^{-3} T^{1/2} \text{ m s}^{-1} \quad (8)$$

where  $T$  is the time in yr. This could result in a significant perturbation on comets far from the Sun. The aphelion velocity of an Oort cloud comet with perihelion distance of 1 AU is  $\sim 0.84 \text{ m s}^{-1}$  while its period is  $4 \times 10^6$  yr, most of which is spent near aphelion. During that time the mean stellar perturbation from the above equation would be  $3.4 \text{ m s}^{-1}$ , capable of raising the comet's perihelion distance to over 25 AU (assuming the velocity perturbation is parallel to the aphelion velocity), outside the observable region. The angular orbit elements would also be expected to change radically. But the maximum possible change in semi-major axis for the same typical perturbation is only 0.05%. Thus comets which leave the planetary region on orbits with large aphelion distances may again be subject to significant changes in angular momentum by passing stars, but not in orbital energy. This could be an important factor in following the evolution of such comets during their lifetimes. The fraction of comets for which this occurs, however, is not large. For comets originating in the cloud and with perihelia inside the orbit of Jupiter, only  $\sim 9\%$  will be returned to orbits with aphelion distances between  $10^4$  and  $10^5$  AU.

It is worthwhile to consider the total velocity perturbation on comets in the cloud over the history of the Solar System. From equation (8)  $\Delta V_{r.m.s.} = 113 \text{ m s}^{-1}$ , which agrees well with previous results<sup>1,7</sup>. This is equal to the circular orbital velocity at  $6.9 \times 10^4$  AU from the Sun or the escape velocity at twice that distance. Thus one would expect the present dynamical limits on the cloud to be of the order of  $10^5$  AU or less. Note that the dimensions of the cloud will shrink with time as the stellar perturbations continue to strip away the outermost shells. The mean aphelion distance of observed new comets entering the planetary region from the cloud has been shown<sup>11</sup> to be  $4.32 \pm 0.12 \times 10^4$  AU. The dynamical limit<sup>12</sup> on the Sun's sphere of influence due to perturbations by the galactic nucleus is of the order of  $2 \times 10^5$  AU.

The perihelion distribution of comets entering the planetary region from the Oort cloud can be obtained by considering the velocity phase space in the plane perpendicular to each comet's heliocentric radius vector, shown in Fig. 1. The component of the comet's aphelion velocity in this plane determines the perihelion distance. Comets are randomly scattered on this plane by stellar perturbations whose r.m.s. magnitude is  $(2/3)^{1/2}$  that given by equation (8). If a comet's initial tangential velocity is given by  $V_{\text{orb}}$  then after a stellar perturbation of  $\Delta V$ , it will have some velocity  $V_{\text{new}}$ . Those comets whose new velocity vectors fall within a relatively small circle around zero transverse velocity ( $1.88 \text{ m s}^{-1}$  for a perihelion of 5 AU and aphelion of  $5 \times 10^4$  AU) will enter the planetary region and possibly be observed. The typical value for  $\Delta V$  is of the order of  $2.8 \text{ m s}^{-1}$  so comets can be expected to be randomly scattered over the near-zero velocity region in phase space. Thus the number in the circle is proportional to the area of the circle, or to its radius squared, that is  $\propto V_t^2$ . But  $V_t \propto q^{1/2}$  so the cumulative number of comets between zero and any value  $q$  is proportional to  $q$ , or  $dN/dq$  is constant. This result has also been demonstrated by Monte Carlo simulations of the problem<sup>13</sup>.

Another implication drawn from the magnitude of the total r.m.s. perturbation is that the orbits of the comets in the cloud have been 'randomized' over the history of the Solar System. Thus it is unlikely that orbital data could be used to discriminate between various theories of cometary origin, that is, formation among the outer planets with subsequent ejection to the cloud, versus formation in satellite fragments of the primordial solar nebula.

Finally, one can also consider the number of comets ejected from the cloud due to single passes of stars through it. Using the estimated population of  $2 \times 10^{11}$  comets and assuming a radius of  $10^5$  AU yields a number density of  $\rho_c = 4.8 \times 10^{-5} \text{ AU}^{-3}$ . Each

star will eject from the cloud comets for which the velocity perturbation is greater than the escape velocity:

$$2GM_*/DV_* > (2GM_\odot/R)^{1/2} \quad (9)$$

where  $D$  is the minimum comet-star distance and  $R$  is the comet-Sun distance. Solving for  $D$  gives

$$D = (2GR/M_\odot)^{1/2} M_*/V_* \quad (10)$$

Assuming a  $1 M_\odot$  star and a relative velocity of  $20 \text{ km s}^{-1}$  one finds  $D = 2.1 R^{1/2}$  where  $R$  is in AU.

From equation (3) there would be  $N_* = 5.4 \times 10^3$  stellar encounters within  $10^5$  AU over the history of the Solar System. Approximating the volume swept out by each star by a cylinder with radius equal to  $D$  at  $R = 5 \times 10^4$  AU and with length equal to the mean chord length through the cloud of  $10^5$  AU gives

$$N_{\text{ejected}} = N_* \pi D^2 10^5 \rho_c = 1.8 \times 10^{10} \quad (11)$$

This is 9% of the estimated cloud population, a small but significant fraction. Note that this is the fraction ejected by single stellar encounters only, and that the cumulative effect of many encounters will eject additional comets.

I thank colleagues at JPL for review of an earlier draft of this paper. This paper presents one phase of work performed at the Jet Propulsion Laboratory/California Institute of Technology under NASA contract NAS 7-100.

## Far UV photolysis of $\text{CH}_4$ - $\text{NH}_3$ mixtures and planetary studies

Alain Boesard & Gérard Toupance

Laboratoire de Physico-Chimie de l'Environnement,  
Université Paris Val de Marne, Avenue du Général de Gaulle,  
94010, Créteil Cedex, France

The far UV photochemistry of  $\text{CH}_4$  and of  $\text{NH}_3$  has been widely studied<sup>1,2</sup> and the primary processes are relatively well known. In contrast no experimental study of far UV photochemistry of  $\text{CH}_4$ - $\text{NH}_3$  mixtures had been published before our preliminary report<sup>3</sup>. We report here new photochemical data on the effect of the mole fraction of  $\text{NH}_3$  on the production of N-containing organics. Photolysis of  $\text{CH}_4$ - $\text{NH}_3$  mixtures at 147 nm leads to the formation of nitriles when the mole fraction of  $\text{NH}_3$  is low and to the formation of amines when the mole fraction of  $\text{NH}_3$  is high. Study of mixtures in which the  $\text{NH}_3$  mole fraction is very low has been particularly emphasized. The main conclusions are that (1) important quantities of nitriles may have been photo-produced on the primitive Earth if a low partial pressure of  $\text{NH}_3$  remained and (2) nitriles are the main N-containing organics that may be photoproduced in the atmosphere of the giant planets.

The far UV photolysis of various  $\text{CH}_4$ - $\text{NH}_3$  mixtures was carried out under a total pressure of 13 mbar into a cylindrical all-pyrex reactor ( $l = 35 \text{ cm}$ ; i.d. =  $4 \text{ cm}$ ) with a low-pressure Xe-lamp attached (window,  $\text{MgF}_2$ ;  $\lambda = 147 \text{ nm}$ , monochromatic; flux emitted =  $8 \times 10^{15} \text{ photon s}^{-1}$ ). The apparatus has been described elsewhere<sup>4</sup>. The reactor was evacuated to a

**Fig. 1** Chromatogram obtained after irradiation of an equimolar  $\text{CH}_4$ - $\text{NH}_3$  mixture during 30 min with a xenon lamp emitting  $8 \times 10^{15}$  photons per second. Solid line,  $\text{CH}_4$  (6.5 mbar)- $\text{NH}_3$  (6.5 mbar); dashed line,  $\text{CH}_4$  (13 mbar). Chromatograms were obtained with a Varian apparatus model 1520 using FID. Chromatographic conditions, glass column (6 mm i.d.  $\times$  3 m) packed with Chromosorb 103 (100–120 mesh). Carrier gas,  $\text{N}_2$  (40 ml  $\text{min}^{-1}$ ).

pressure  $< 10^{-5}$  mbar before each experiment; care was taken to ensure that there were no mercury-containing devices in any part of the apparatus. Samples were analysed mostly by gas chromatography (FID detector).

Two series of experiments were performed. In the first the irradiation time was 30 min and the mole fraction of  $\text{NH}_3$  in the mixture ranged from 0.1 to 1; in the second the respective values were 7 min, and 0.01 to 0.1. The irradiation times were chosen to ensure a significant synthesis of products and a negligible decomposition of the initial compounds,  $\text{NH}_3$  being the most critical, during the experiment.

The solid curve (Fig. 1) applies to an equimolar  $\text{CH}_4$ - $\text{NH}_3$  mixture irradiated for 30 min: amines, nitriles and hydrocarbons are synthesized. Gas chromatography on a Porapak Q package shows that the hydrocarbons are mainly saturated,  $\text{C}_2\text{H}_6$  and  $\text{C}_3\text{H}_8$  representing respectively more than 99% of the  $\text{C}_2$  and  $\text{C}_3$  hydrocarbons. The dashed curve applies to  $\text{CH}_4$  irradiated for 30 min at the same total pressure. Figure 1 shows that  $\text{NH}_3$  in the mixture strongly inhibits the synthesis of hydrocarbons. A gas chromatography on a Porapak Q package has shown that this inhibitory effect of  $\text{NH}_3$  is much more important for unsaturated hydrocarbons than for saturated ones.

$\text{CH}_3\text{NH}_2$ ,  $\text{C}_2\text{H}_5\text{NH}_2$ ,  $\text{HCN}$ ,  $\text{CH}_3\text{CN}$ ,  $\text{C}_2\text{H}_5\text{CN}$  and many aliphatic hydrocarbons have been definitively identified as products of the photolysis. As quantitative gas chromatographic analysis of  $\text{HCN}$  is not possible in the presence of  $\text{NH}_3$ , a colorimetric titration<sup>5</sup> has been achieved for this compound. For a  $\text{CH}_4$ - $\text{NH}_3$  mixture where the mole fraction of  $\text{NH}_3$  is 0.1, the amount of  $\text{HCN}$  synthesized has been found to be approximately equal to the amount of  $\text{CH}_3\text{CN}$  synthesized during the same experiment. There has not been a search for hydrazine.

Figure 2 shows how the mole fraction of  $\text{NH}_3$  affects the synthesis of  $\text{CH}_3\text{CN}$  and  $\text{CH}_3\text{NH}_2$ . An opposite effect is evident: increasing the mole fraction of  $\text{NH}_3$  strongly increases the synthesis of  $\text{CH}_3\text{NH}_2$  but strongly decreases the synthesis of  $\text{CH}_3\text{CN}$ . In fact, for mole fractions of  $\text{NH}_3 \leq 0.2$ , no  $\text{CH}_3\text{NH}_2$  has been detected by gas chromatography. To have a better limit of detectability, a spectrophotofluorimetric analysis of  $\text{CH}_3\text{NH}_2$  using the fluorecamine<sup>6</sup> technique has been performed. For a mixture containing a mole fraction of  $\text{NH}_3$  equal to 0.1, we have

found that the quantity of  $\text{CH}_3\text{NH}_2$  synthesized was at best 20 nmol, that is 7% of that of  $\text{CH}_3\text{CN}$ .

The second series of experiments, using mole fractions of  $\text{NH}_3$  in the range 0.01–0.1, has been performed to determine more precisely the portion of the curve plotted with a dashed line on Fig. 2. The results are shown in Fig. 3. Synthesis of  $\text{CH}_3\text{CN}$  is efficient even when the mole fraction of  $\text{NH}_3$  is very low. There was no search for amines.

The photochemistry involved in these experiments, especially for the synthesis of nitriles, is not yet clear. At 147 nm both  $\text{CH}_3$  and  $\text{CH}_2$  may be photoproducts from  $\text{CH}_4$  (ref. 7) (the relative amount of the two species is not known) while both  $\text{NH}_2$  and  $\text{NH}$  may be photoproducts from  $\text{NH}_3$  (ref. 8). However, as molar absorption coefficients<sup>9</sup> at 147 nm, are respectively  $0.2 \text{ cm}^{-1} \text{ atm}^{-1}$  for  $\text{CH}_4$  and  $80 \text{ cm}^{-1} \text{ atm}^{-1}$  for  $\text{NH}_3$ , in every considered mixture  $\text{CH}_4$  absorbs only a minor part of the incident light (that is 2% or less when the  $\text{NH}_3$  mole fraction is 0.1 or above). Consequently, the predominant radicals in the system are:  $\text{NH}_2$  and  $\text{NH}$  photoproducts from  $\text{NH}_3$ , and  $\text{CH}_3$  mainly produced through reaction of  $\text{CH}_4$  with energetic H atoms resulting from the photodissociation of  $\text{NH}_3$ :

$\text{CH}_2$  which can be produced only from the photodissociation of  $\text{CH}_4$  is present at a lower concentration.

The key step for the synthesis of hydrocarbons is the formation of  $\text{C}_2\text{H}_6^*$  through:

It seems likely that the reaction pathway for  $\text{CH}_3\text{NH}_2$  synthesis combines  $\text{CH}_3$  and  $\text{NH}_2$ . The production of nitriles is more difficult to explain. A reaction pathway in steps must be invoked but unfortunately there is very little knowledge of the reactions of the  $\text{NH}$  radical nor of the chemistry of intermediate species which should be considered, such as  $\text{CH}_2\text{NH}$ ,  $\text{CH}_3\text{NH}$  or  $\text{CH}_3\text{CHNH}$ . In fact, although the production of  $\text{HCN}$  has been reported in similar experiments<sup>10</sup>, no reaction pathway has been proposed.

Nevertheless, it seems likely that the photodissociation of  $\text{CH}_4$  is not necessary for the production of nitriles because first,  $\text{HCN}$  is synthesized in experiments performed at 185 nm where photodissociation of  $\text{CH}_4$  cannot occur<sup>10</sup>; and second, because of the calculated quantum yield of synthesis of  $\text{CH}_3\text{CN}$ , relative to the photons absorbed by  $\text{CH}_4$ , obtained in our experiments.

**Fig. 2** Influence of the mole fraction of  $\text{NH}_3$  on the synthesized quantities of acetonitrile and methylamine. In all these experiments, there is total absorption of the incident UV light.

**Fig. 3** Influence of the mole fraction of  $\text{NH}_3$  on the synthesis of acetonitrile. Analysis has been performed by GC on Porapak Q support. The chromatogram obtained and analytical conditions have been previously reported<sup>4</sup>. Absorption of the incident UV light is not total, except when the mole fraction of  $\text{NH}_3$  is 0.1.

Let us assume, as an extreme situation, that the photodissociation of  $\text{CH}_4$  at 147 nm gives only  $\text{CH}_2$ . As long as  $\text{CH}_4$  and  $\text{NH}_3$  remain the most concentrated species, the most frequent reactions of  $\text{CH}_2$  are (3) and:

The kinetic parameters of reactions (3) and (4) are not known; however, as reaction (3) is very exothermic ( $\Delta G^\circ = -84.4 \text{ kcal mol}^{-1}$ ) its probability is  $\sim 1$  when a collision occurs. Consequently, in a  $\text{CH}_4\text{-NH}_3$  mixture where the mole fraction of  $\text{NH}_3$  is 0.1, <10% of the  $\text{CH}_2$  produced from photodissociation of  $\text{CH}_4$  may react through reaction (4). If we assume that some of the products formed in reaction (4) are involved in the synthesis of  $\text{CH}_3\text{CN}$ , we can conclude that the quantum yield of synthesis of  $\text{CH}_3\text{CN}$  through reaction (4), calculated with respect to the photons absorbed by  $\text{CH}_4$ , should be, at best, 0.1. It is probably very much less. As we have found that the experimental quantum yield of synthesis of  $\text{CH}_3\text{CN}$ , calculated in respect of the photons absorbed by  $\text{CH}_4$ , is 0.4, we conclude that reaction (4) is not important for the synthesis of  $\text{CH}_3\text{CN}$ . As the second important reaction of  $\text{CH}_2$ , reaction (3), leads to the same product as reaction (2), we also conclude that production of  $\text{CH}_2$  is not needed to explain the bulk of the results we have obtained. Finally, as  $\text{CH}_3$  may also be produced from reaction (1) (that is from photodissociation of  $\text{NH}_3$ ) as well as from photodissociation of  $\text{CH}_4$ , it may be assumed that photolysis of  $\text{CH}_4$  does not introduce any significant specificity in the system.

Figure 4 represents the quantum yield of synthesis of  $\text{CH}_3\text{CN}$  and of  $\text{CH}_3\text{NH}_2$  calculated from the data reported in Figs 2 and 3, and with respect to the photons absorbed by  $\text{NH}_3$  during each experiment. The quantum yield of synthesis of  $\text{CH}_3\text{CN}$  is shown to increase continuously when the mole fraction of  $\text{NH}_3$  decreases, whereas a drastically opposite effect is observed for  $\text{CH}_3\text{NH}_2$ . Experimental constraints limited our study to mixtures in which the mole fraction of  $\text{NH}_3$  was  $\geq 0.01$ . Nevertheless, we conclude that the quantum yield of synthesis of  $\text{CH}_3\text{CN}$  continues to increase slowly when the mole fraction of  $\text{NH}_3$  is decreased to  $<0.01$ . A limit value of  $3 \times 10^{-2}$  can be accepted for very low mole fractions of  $\text{NH}_3$ . We have also reported that

$\text{HCN}$  is synthesized with the same efficiency as  $\text{CH}_3\text{CN}$  when the mole fraction of  $\text{NH}_3$  is 0.1. If we assume that the same results apply at lower mole fractions of  $\text{NH}_3$ , the limit value for the total quantum yield of synthesis of nitriles at very low mole fractions of  $\text{NH}_3$  is probably  $\sim 5 \times 10^{-2}$ .

The new photochemical data on the qualitative and quantitative production of N-containing organics in  $\text{CH}_4\text{-NH}_3$  mixtures may be applied to the jovian troposphere and to the atmosphere of the primitive Earth.

The photochemistry of the atmosphere of Jupiter is generally approached by computer modelling based on photochemical data from  $\text{CH}_4$  and  $\text{NH}_3$ . Many difficulties occur in the building up of a convenient photochemical model mainly due to the lack of numerous kinetic data and even the lack of reaction pathways that would be considered. Amines are the only N-containing organics which are considered in such calculations<sup>11-13</sup>. The present experimental results show that, to a large extent this assumption is wrong.

In fact at altitudes where UV light may be absorbed by  $\text{NH}_3$  (that is middle troposphere), the  $\text{NH}_3$  mixing ratio calculated by respect to  $\text{CH}_4$  is  $\sim 10^{-4}$ . The shape of the curves in Fig. 4 suggests that the UV photosynthesis of nitriles is far more efficient than the UV photosynthesis of amines. However, this assumption must be discussed with respect to the wavelength of the UV light and to the  $\text{H}_2$  content of the mixture.

In our experiments both  $\text{NH}$  and  $\text{NH}_2$  are produced by photolysis of  $\text{NH}_3$ . This is possible only for wavelengths shorter than 160 nm. At longer wavelengths only  $\text{NH}_2$  is produced. We have previously reported<sup>4</sup> the effect of important quantities of  $\text{H}_2$  on the photochemical synthesis (147 nm) of nitriles from  $\text{H}_2\text{-CH}_4\text{-NH}_3$  mixtures where the  $\text{NH}_3$  mole fraction relative to  $\text{CH}_4$  was 0.5. The increase of the amount of  $\text{H}_2$  decreases the synthesis of the nitriles. We do not have similar data for amines; however, the same effect can be expected if we assume that most of the synthesis of N-containing organics is initiated by  $\text{NH}$  and  $\text{NH}_2$  photoproducted from  $\text{NH}_3$ . In the presence of  $\text{H}_2$  these species are neutralized into  $\text{NH}_3$  which should probably decrease the yield of synthesis of the different N-containing organics in similar proportions.

**Fig. 4** Influence of the mole fraction of  $\text{NH}_3$  on the quantum yield of formation of acetonitrile and of methylamine. These curves have been built from the experimental results shown in Figs 2 and 3. The quantum yields are calculated with respect to the photons absorbed by  $\text{NH}_3$ .

The present data may contribute to the study of the evolution of the atmosphere of the primitive Earth in the limits of the reducing atmosphere hypothesis. They show that the presence of large amounts of  $\text{NH}_3$  were not necessary for the photochemical synthesis of nitriles. If a low molar mixing ratio of  $\text{NH}_3$  had remained for a significant time, an efficient production of these nitriles may have occurred.  $10^{12}$  mol of nitriles per year would be produced only with photons of wavelengths ranging from 150 to 160 nm (quantum yield of production of nitriles =  $5 \times 10^{-2}$ ; present solar flux). As a cyano group cannot be easily destroyed<sup>14</sup> by the UV light which reaches the altitude where it is produced, most of the synthesized nitriles would have reached the oceans. The presence of other gases such as  $\text{N}_2$  or  $\text{H}_2\text{O}$  in the atmosphere should be tested.  $\text{CH}_4\text{-NH}_3$  and  $\text{CH}_4\text{-NH}_3\text{-H}_2\text{O}$  gaseous mixtures have been irradiated (147 nm) in the same experimental conditions: the rate of production of HCN is about the same in both cases.

This study has been supported by the French Space Agency, CNES. We thank Dr J. P. Ferris for helpful comments.

## Trace element determination by capacitive discharge atomic absorption spectrometry

C. L. Chakrabarti, C. C. Wan, H. A. Hamed & P. C. Bertels

Department of Chemistry, Carleton University, Ottawa, Ontario, Canada K1S 5B6

Conventional instrumental analytical techniques require careful calibration of the instrument with chemically analysed standards or synthetic standards of known composition. When analyses of miscellaneous materials are required, providing the required range of standards becomes impossible. As a way to an absolute method of atomic absorption analysis, L'vov<sup>1</sup> suggested using a capacitive bank as a source of electrothermal energy for heating graphite atomizers. We describe here a new analytical technique which uses a capacitor bank for electrothermal heating of an anisotropic pyrolytic tube atomizer in atomic absorption spectrometry producing very fast rates of heating and an isothermal condition, both in space and in time<sup>1,2</sup>, and uses a direct relationship: peak absorbance = constant  $\times$  mass of analyte, thereby dispensing with analytical calibration curves. Sensitivity is almost independent of the matrix and matrix interferences are greatly reduced. Background correction is not required.

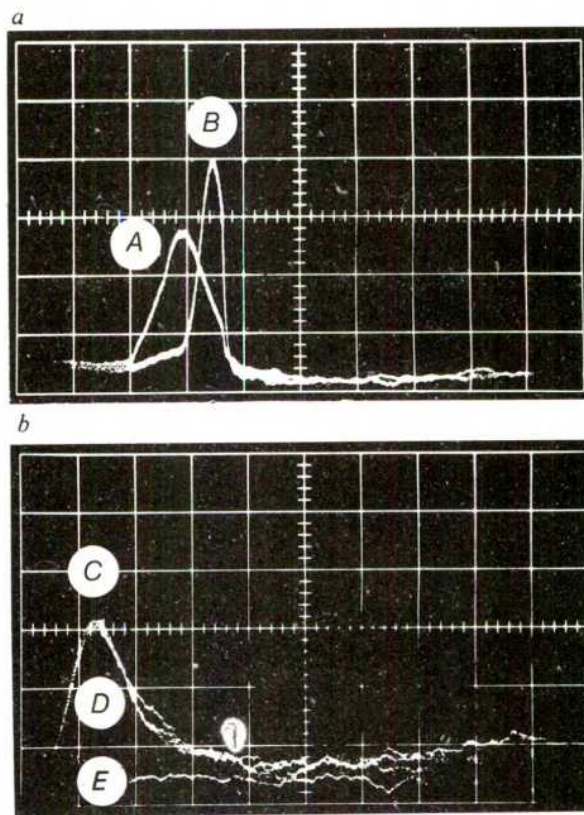

Equation (1) is a modified version of that given by L'vov<sup>3</sup>.

$$A_{\text{peak}} = \alpha(T^{0.7}/SP)M = \beta M \quad (1)$$

where  $A_{\text{peak}}$  is the peak absorbance,  $\alpha$  a coefficient determined by atomic and spectroscopic constants and by experimental conditions,  $T$  the absolute temperature,  $S$  the cross-sectional

area,  $P$  the pressure inside the graphite tube,  $M$  is the mass of the analyte and  $\beta$  the proportionality constant. The apparatus and its operation have been described elsewhere<sup>1</sup>.

Absorption pulses are recorded with a model 549 storage oscilloscope (Techtronix) fitted with a type 1A7A high-gain differential plug-in. The signal trace is photographed with a Polaroid camera (Tektronix). Three standard solutions of the analyte of different concentrations were analysed, three times each, and the arithmetic mean of these determinations was averaged to provide the value for  $\beta$ . The concentrations of the unknown samples were determined from their absorbance values obtained using the above conditions and suitable mass of solid samples or  $5.0 \times 10^{-6}$  dm<sup>3</sup> volume of the dissolved samples as appropriate and solving equation (1) for the unknown mass of the analyte element.

**Fig. 1** a, Oscilloscopic traces for  $5.0 \times 10^{-13}$  kg of Pb (as nitrate) atomized at a heating rate of  $1.3 \text{ K ms}^{-1}$  and temperature of 2200 K. Curve A, Pb (as nitrate) in 0.5% (wt/v) NaCl aqueous solution. Curve B, Pb (as nitrate) in an aqueous solution. Vertical scale, 0.1 absorbance per scale division. Horizontal scale, 500 ms per scale division. Curve E, the blank made of an aqueous solution of 0.5% (wt/v) NaCl. Vertical scale, 0.1 absorbance/scale division. Horizontal scale, 100 ms per scale division. Pb  $\lambda$  283.3 nm.

Table 1 shows the experimental conditions used, and also, the precision of the proportionality constant for equation (1). From Table 1, within-the-day precision of the mean is seen to have varied from 2.5 to 7.6% r.s.d. These relatively low values of the % r.s.d. are a measure of the validity of the proportionality expressed by equation (1). The large variations in the proportionality constants between the days were mainly due to change in the resistance of the atomizer circuit caused by change in the contact resistance between graphite electrodes and graphite tubes—the change was considerable with new tubes inserted at the beginning of each day. Substitution of automatic electronic

**Table 1** Experimental conditions and the precision of the proportionality constant ( $\beta$ ) for equation (1)

| 2       | Cd      | 228.8              | 2,300                       | $9.90 \times 10^{13}$   | 7.6       |

\* Three different concentrations, each concentration was determined three times, making nine determinations. The value represents % relative standard deviation of the mean of three determinations.

control of resistance for the present manual control will improve both the between-day reproducibility and the within-the-day precision—the latter is largely determined by change in resistance due to change in contact tension and in the porosity of graphite with firings.

Table 2 presents the results of analysis. Table 2b shows a comparison of the results obtained by the technique with those obtained by the conventional graphite furnace atomic absorption spectrometry (GFAAS) using the Perkin-Elmer Heated Graphite Atomizer (HGA) 76B and optimized experimental conditions. Table 2b shows that results of the conventional GFAAS suffer from extremely severe depression by the matrix, whereas the matrix interferences have been almost completely eliminated by this technique. Another problem with commercial graphite furnaces is that they are non-isothermal, both spatially and temporally<sup>4</sup>.

The sensitivity of the technique is almost independent of matrix. This is important because analysis by GFAAS suffers from severe matrix interferences. There is also another significant difference—background correction is not required with this technique. Because analysis of complex materials by the conventional GFAAS usually requires removal of interfering matrices (including those that give extremely intense background absorption) from samples before the determination of the analytes, background correction represents a serious limiting factor in the speed and accuracy of analysis by the conventional GFAAS. Even removal of the bulk of the interfering matrices in the charring (pyrolysis) stage of the heating cycles of the conventional GFAAS by using the time-resolved selective volatilization and atomization technique<sup>5,6</sup> requires precise determination of the heating programme to remove the bulk of the matrix without any loss of the analytes, and correction for the residual background absorption by the background correction technique. The solid-sampling technique<sup>6</sup>, applied with this technique eliminates the large dilution factor involved in the solution-sampling technique, and thereby enhances greatly the relative sensitivity. This is in addition to the large enhancements in the absolute sensitivity of this technique, for example, for Cu, Ni and Al, the enhancements are 27-fold, 24-fold and 20-fold, respectively<sup>2</sup>.

The effect of high heating rates and isothermal atomization is seen from Fig. 1a, which shows oscilloscopic traces of  $5 \times 10^{-13}$  kg of Pb atomized at a heating rate of  $1.3 \text{ K ms}^{-1}$  and an atomization temperature of 2,200 K, using the conventional GFAAS but with an anisotropic pyrolytic graphite tube. In the chloride matrix the lead signal appears earlier in time and, hence, the lead appearance temperature is lower; also the pulse amplitude is lower than that of the aqueous solution of lead nitrate without the matrix. Figure 1b shows oscilloscopic traces for the above systems using the capacitive discharge technique, a heating rate of  $40 \text{ K ms}^{-1}$ , and isothermal atomization at a

† The relative standard deviation of the mean of five replicate determinations by the capacitive discharge technique = 12%.

Fig. 2 Recoveries of Cd as a function of heating rate from an aqueous solution containing NaCl  $1.0 \times 10^{-8}$  kg + MgCl<sub>2</sub>  $1.2 \times 10^{-9}$  kg + CaCl<sub>2</sub>  $4.0 \times 10^{-10}$  kg as a function of the heating rate. Cd  $\lambda$  228.8 nm. Cd =  $4.0 \times 10^{-14}$  kg. Atomization temperature, 1,900 K.

temperature of 2,200 K (same as that of Fig. 1a); curve E is for the blank containing an aqueous solution of 0.5% (wt/v) NaCl, and shows that the background absorption due to the NaCl matrix is completely absent, which is highly significant. Figure 1b shows that the two absorption pulses are identical in both amplitudes and areas, and the matrix effects have been completely eliminated. In Fig. 1b the lead signal appears much later in time (compared with Fig. 1a), and hence, the appearance temperature for lead is considerably higher than that in Fig. 1a. In Fig. 1b the considerably higher appearance temperature for Pb and atomization in constant temperature are crucial for eliminating chloride matrix interferences. In Fig. 1a, atomization of lead occurred in non-isothermal conditions at a temperature which was considerably lower than that in Fig. 1b and at a time when the temperature of the atomizer increased at a very rapid rate from 600 to 2,200 K; hence, the pressure inside the graphite tube changed from 1 to 3.7 atm, which resulted in partial expulsion of the lead chlorides vapour; also the extent of dissociation of lead chlorides to lead atoms was less at the lower temperature. It is concluded that the elimination of the matrix effect in Fig. 1b is due to atomization at a constant temperature and at a much faster rate of heating with the technique.

Figure 2 shows the recoveries of Cd from an aqueous solution of NaCl + MgCl<sub>2</sub> + CaCl<sub>2</sub> matrices as a function of heating rates at the isothermal atomization temperature of 1,900 K. Even at the highest heating rate used (63 K ms<sup>-1</sup>), the recovery curve is seen to rise slightly, indicating a need for still higher heating rates for greater recoveries.

We conclude that even with the present laboratory-made instrumentation, the technique gives fairly accurate and precise results, which should improve with better instrumentation.

The technique with its simplified and shortened analytical procedure should save considerable time and cost per analysis. The limitation of this technique is that in the solid-sampling technique, the small sample (mg) requirement may present a sampling problem if the solid sample is inhomogeneous.

## Forces between mica surfaces bearing layers of adsorbed polystyrene in cyclohexane

Jacob Klein

Polymer Department, Weizmann Institute of Science, Rehovot, Israel

Direct measurements of the forces acting between polymer surface phases adsorbed at interfaces have only recently been reported<sup>1-3</sup>. These were carried out in good solvents and showed that repulsive forces were acting between the adsorbed layers; these forces increased monotonically as the surfaces approached each other. In certain conditions, however, for example, those leading to the flocculation of sterically stabilized colloidal systems, one expects the surfaces bearing the adsorbed phases to attract before repelling each other<sup>4,5</sup>. I have measured the forces acting between two curved mica surfaces immersed in cyclohexane at 24 °C (a worse than  $\theta$  solvent at this temperature), each bearing a surface layer of adsorbed polystyrene ( $M_w = 6 \times 10^5$ ). No forces are observed at surface separations larger than about three radii of gyration of the polymer; on closer approach a strong attraction develops between the surfaces, changing to an ultimate repulsion as the surfaces approach closer than about one radius of gyration. Between times of a few minutes and several hours the forces are stable, well behaved and reproducible.

The experimental technique (Fig. 1) is an extension of that developed by Tabor *et al.*<sup>6,7</sup>, and recently modified by Israelachvili and Adams<sup>8</sup>, to measure (1) the forces  $F(D)$  acting between two curved mica surfaces a distance  $D$  apart; (2) the mean refractive index  $n(D)$  of the medium separating the surfaces.

$F(D)$  was first determined between the mica surfaces in pure cyclohexane; polystyrene solution was then added to the cell, to a final concentration of  $7 \pm 2 \times 10^{-6}$  g ml<sup>-1</sup>. After 10 h incubation in the polymer solution,  $F(D)$  was measured both in compression and decompression; measurements were repeated in the solution over a period of some hours, following which the polymer solution was entirely removed (save for ~1 ml between the mica surfaces) and replaced by pure cyclohexane. The surface-surface forces were then measured at intervals of between 5 min and several hours, and at compression/decompression rates of between 20–60 min per cycle, over a period of 48 h. The temperature of all experiments was  $24 \pm 0.5$  °C.

The results are shown in Fig. 2. No forces are observed as the surfaces approach from  $D \approx 300$  nm down to  $D \approx 60$  nm; on closer approach an attractive force arises between the surfaces, and on further decreasing  $D$  they jump from A (Fig. 2b) to a new stable position at B (such jumps are expected<sup>6</sup> whenever  $dF/dD > K$ , the force constant of the spring supporting the lower mica surface—see Fig. 1). Further approach results in a strong repulsion. On separation (decompression) the surfaces jump from C to a new stable position at E. The region AC is a region of instability ( $dF/dD > K$ ), where  $F(D)$  and  $n(D)$  cannot be determined<sup>8</sup>. The 'jumps' (A  $\rightarrow$  B, C  $\rightarrow$  E) are not instantaneous, and up to 300 s are required for new stable positions to be established; this is interpreted as the time taken by the opposing adsorbed layers to interdiffuse (on compression) or disentangle (on decompression). The forces are stable, and within the estimated errors, reversible and reproducible over the several compression/decompression cycles. In particular, the surfaces could be held in a strongly repulsive region around  $D \approx 14$  nm under a fixed force for up to 3 h with no resulting change in the separation.

5 Nakahara, T. & Chakrabarti, C. L. *Anal. Chem. Acta* **104**, 99–111 (1979).

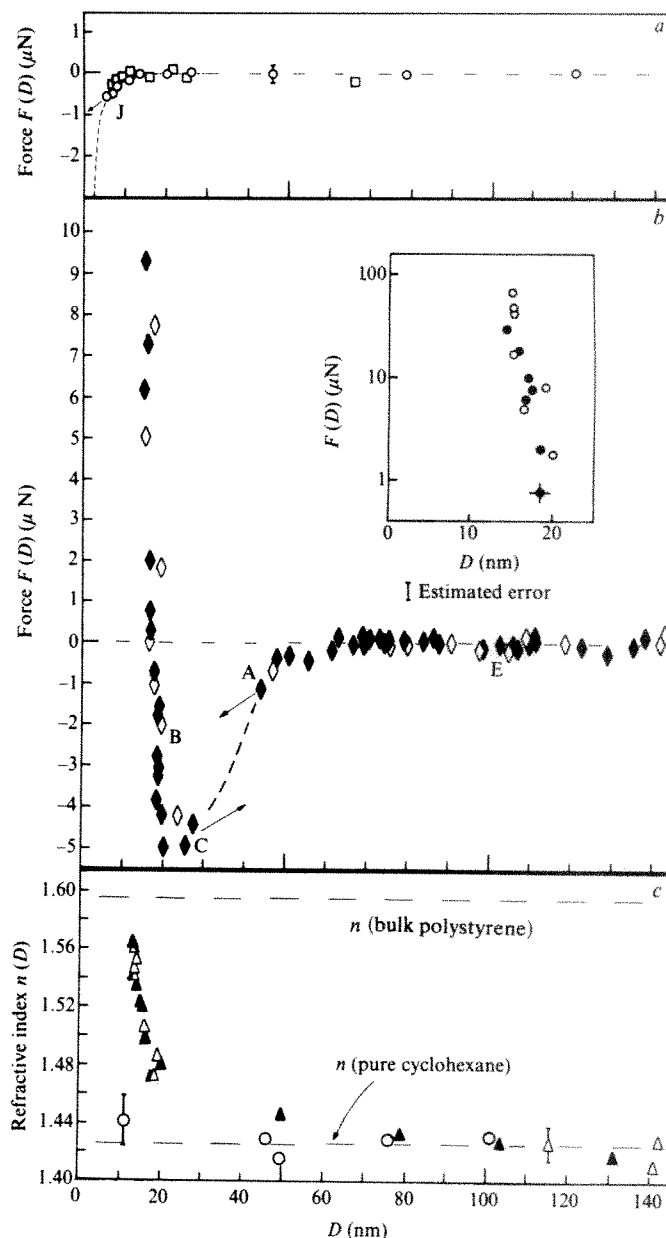

6 Chakrabarti, C. L., Wen, C. C. & Li, W. C. *Spectrochim. Acta* **36B**, 93–105 (1980).

The refractive index  $n(D)$  of the medium separating the mica surfaces varied between  $n = 1.56 \pm 0.02$  at  $D = 14$  nm and  $n = 1.43 \pm 0.012$  for  $D \geq 80$  nm (Fig. 2c). The values of  $n$  were determined, following incubation, in the polymer solution, and were unchanged on replacing the solution by pure solvent, and up to 48 h later. From the bulk refractive indices of cyclohexane (1.426) and polystyrene (1.595) the value of  $n$  ( $D = 14$  nm) corresponds to an adsorbance on each mica surface of around  $6 \text{ mg m}^{-2}$  of polymer. This compares with equilibrium adsorbances of  $3\text{--}8 \text{ mg m}^{-2}$  for polystyrene adsorbed onto various substrates from cyclohexane at the  $\theta$  temperature<sup>9</sup>.

In the conditions of only moderately high polymer molecular weight and extremely low bulk concentration of polymer used in the present study, the polymer solution, though considerably below the Flory  $\theta$ -temperature for this system ( $35^\circ\text{C}$ ), is above its cloud-point temperature<sup>5,10</sup>. Thus no phase-separation occurs<sup>10</sup> (other than adsorption); polymer dimensions are expected to be somewhat smaller than their unperturbed value<sup>5,11</sup>. Because very long times may be required before an adsorbed layer reaches equilibrium, we cannot be sure that, given much longer times, the system may not undergo further change. The fact that replacing the polymer solution by essentially pure solvent does not significantly change the adsorbed layer suggests that the adsorption may behave irreversibly. The onset of interaction between the surfaces at  $D \approx 60$  nm indicates that significant overlap between the opposing polymer layers begins at this value of  $D$ , corresponding to adsorbed layers extending some 30 nm from each mica surface. This compares with an unperturbed radius of gyration  $R_g = 21$  nm for this polymer<sup>13</sup>, and with ellipsometrically<sup>9</sup> and viscometrically<sup>12</sup> measured equilibrium layer thicknesses of 40 nm for poly-

**Fig. 1** Section of the apparatus used to measure forces between mica surfaces in a liquid medium. The surfaces are mounted in a crossed-cylinder configuration (inset) on cylindrical quartz lenses, within a glass cell (volume  $\sim 150$  ml); their separation  $D$  is controlled (to 0.2 nm) by the rigid arms A, B, using a three-stage mechanism (two micrometers and a piezoelectric crystal) similar to that previously described<sup>8</sup>. The method is based on an optical technique utilizing white-light multiple-beam interferometry, which can measure both  $D$  (to 0.3 nm) and the refractive index  $n(D)$  of the medium separating the surfaces, as well as their radii of curvature<sup>6,7</sup>. The top mica surface is directly mounted on the rigid arm B, while the bottom surface is mounted on A through a leaf spring of force constant  $K$  ( $75 \text{ N m}^{-1}$ ). By measuring the change in  $D$  in response to known, applied relative displacements of the rigid arms A and B,  $F(D)$  may be determined<sup>8</sup>. The glass cell is mounted within an airtight stainless steel box, which is in turn placed on a mechanically insulated platform within a thermally insulated chamber. Scale bar, 2 cm.

**Fig. 2** Forces  $F(D)$  and refractive index  $n(D)$  between curved mica surfaces in cyclohexane (Fluka, spectroscopic grade) at  $24.0 \pm 0.5^\circ\text{C}$ . **a**, Forces between bare mica surfaces in pure cyclohexane. At  $J(7 \pm 1 \text{ nm})$  the surfaces jump into contact within  $\pm 0.3$  nm of their air contact position. Mica surfaces (where  $R$  is the mean radius of curvature of mica):  $\square$ ,  $R = 0.35 \times 10^{-2} \text{ m}$ ;  $\circ$ ,  $R = 0.66 \times 10^{-2} \text{ m}$ . The broken line is the theoretical Van der Waals force  $F(D) = -AR/6D^2$ , with  $R = 0.66 \times 10^{-2} \text{ m}$  and a Hamaker constant  $A = 1.4 \times 10^{-20} \text{ J}$ , estimated from optical data for mica in cyclohexane. **b**, Forces between the curved mica surfaces of **a** ( $R = 0.66 \times 10^{-2} \text{ m}$ ) following 10 h incubation in a polystyrene cyclohexane solution. Solutions were prepared by overnight stirring of the polystyrene (Pressure Chemicals,  $M_w = 5.99 \times 10^5$ ,  $M_w/M_n \leq 1.06$ ) in cyclohexane, followed by 1-h ultracentrifugation at  $160,000g$  before use. The inset extends the range of  $F(D)$  on a semi-log plot.  $\diamond$ ,  $\circ$ , Forces measured in the polymer solution;  $\blacklozenge$ ,  $\bullet$ , forces following replacement of solution by pure solvent. At A, C the surfaces jump to new stable positions B, E (see text); AC (broken curve) is a region for which  $\partial F/\partial D > K$  and  $F(D)$  cannot be measured<sup>8</sup>. **c**, Refractive index  $n(D)$ , of the medium separating the mica surfaces.  $\circ$ , in pure cyclohexane.  $\Delta$ , in solution, following 10-h incubation.  $\blacktriangle$ , 20–44 h after replacing the polymer solution by pure solvent.

styrene (of similar molecular weight) adsorbed from cyclohexane onto various surfaces in  $\theta$  conditions.

The initially attractive nature of the interactions, however, is to be expected: it arises because the polymer molecules adsorbed on each mica surface have a much greater affinity for those adsorbed on the opposing surface, than they do for the solvent molecules. As Flory has shown<sup>5</sup>, bringing two polymer-segment distributions into overlap in worse than  $\theta$  conditions (a negative second virial coefficient) results in a negative free energy change. Thus, on initial overlap, an attractive force arises between the surfaces; as they approach to much closer than a radius of gyration, the compression of the adsorbed layers by the mica surfaces leads to extensive configurational constraints on the polymer molecules<sup>4</sup>, resulting in the ultimate strong repulsion observed at  $D \leq 18$  nm.

Over the range of times and experimental parameters described, the present results indicate that: (1) in certain conditions the steric repulsion observed when two adsorbed polymer layers are mutually compressed is preceded by an attractive region; (2) the onset of steric interaction between the adsorbed layers may take place at surface separations comparable with the polymer dimensions and with layer thicknesses measured by other means; and (3) the polymer adsorption may be an irreversible process.

I thank Professor A. Silberberg for encouragement, interest and helpful discussions; also the design and workshop staff of the Weizmann Institute for technical assistance, and Dr J. N. Israelachvili for useful suggestions. This work was partly supported by the Basic Research Division of the Israel Academy of Sciences.

## Deep-seated iron ores from banded-iron formation

R. C. Morris, M. R. Thornber & W. E. Ewers

Division of Mineralogy, Institute of Earth Resources, CSIRO, Wembley, Western Australia 6014, Australia

Very large iron ore deposits have formed in many parts of the world, evidently by the supergene alteration of Precambrian banded-iron formation (BIF). Some of these deposits extend to great depths, ranging to 2,400 m at Krivoyrog<sup>1</sup>, beyond the likely reach of oxygenated water. We propose here, on the basis of studies in the Hamersley Ranges, Western Australia, a mechanism for deep-seated ore formation in which electronic conduction through the magnetite layers in BIF connects a cathodic region near the surface, where oxygen is reduced, to an anode at depth, where iron (II) from magnetite, carbonates and silicates is oxidized and precipitated as iron (III) hydroxides. The electrical circuit is completed by ionic conduction through groundwaters. The model is based broadly on a mechanism suggested by Sato and Mooney<sup>2</sup> to explain self-potentials associated with sulphide ore bodies. It is based more specifically on a model demonstrated by Thornber<sup>3</sup> for the

weathering of massive nickel-iron sulphide deposits at Kambalda, Western Australia, but with substantial differences in the physical situation and the reactions at depth.

The iron ore reserves of the Hamersley Iron Province exceed  $33 \times 10^9$  tonnes, much of it contained in huge ore bodies, some of them exceeding 5 km along strike and extending below the present water table to as much as 400 m down dip. They conform to the bedding of the host BIF and, in common with many ore bodies of this kind throughout the world, grade from >60% Fe in ore to <30% Fe in BIF over distances that are always negligible in relation to the size of the ore body and sometimes much less than a metre.

BIF in the Hamersleys is characterized by compositional layering of the centimetre scale in mesobands, some of them magnetite-rich, alternating with others containing chert, haematite, magnetite, silicates and carbonates in varied proportions. Many of these mesobands can be traced individually for hundreds of kilometres<sup>4</sup>.

Morris<sup>5</sup> has provided petrographical evidence that the Hamersley orebodies, in general, have formed from BIF by a combination of residual enrichment of the original iron oxides (magnetite, now martite, and primary haematite) by removal in solution of silica and other gangue, together with replacement of part of this gangue by hydrous iron oxide.

A key factor in the formation of ore at depth by such a process is the electrical conductivity of the magnetite-rich layers in BIF, and this may explain Dorr's<sup>6</sup> observation that ores "form best from the oxide facies iron-formation in most places of the world".

Table 1 lists some field and laboratory resistivity measurements which indicate that BIF is highly conductive along the layers of magnetite. This conductivity is retained even where the magnetite has been partially altered by weathering. Thus the BIF can be considered as an adequate conductor to allow higher oxidation potentials to penetrate to considerable depths as shown in Fig. 1a. The cathode, with a potentially vast area exposed along strike, comprises magnetite in contact with waters oxygenated by the atmosphere. Here electrons drawn from below would be consumed by the reduction of oxygen, summarized by the reaction:

The reaction that can take place at anodic surfaces of magnetite at depth, remote from sources of atmospheric oxygen, is:

The supply of  $\text{Fe}^{2+}$  to the anode, mainly from the dissolution of iron (II) minerals, all of the carbonates and silicates, and some of the magnetite, is facilitated by the release of acid in the hydrolysis reaction which will occur close to the anode surface:

The chief apparent difficulty with this model is that galvanic processes would normally favour near-surface oxidation, that is, with the anode and cathode close together; for example, where an iron bar immersed in damp soil corrodes through near the soil-air interface. However, our experimental data, as well as field and mineragraphic observations, indicate that the

Table 1 Some resistivity measurements on banded-iron formation

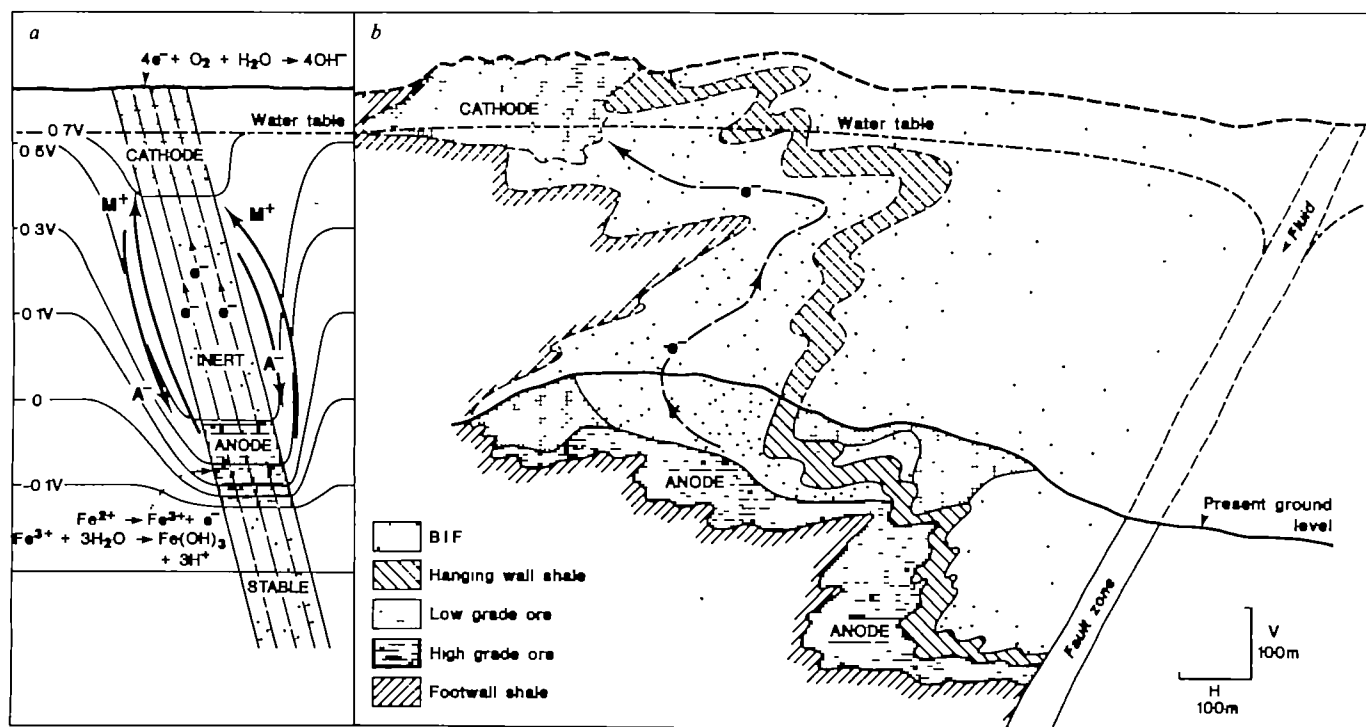

Fig. 1 a, Cross-section illustrating the proposed electrochemical model for the formation of iron ore at depth. Magnetite layers in the BIF provide electron paths between cathode and a deep-seated, initially porous, anodic zone. Cations ( $M^+$ ) and anions ( $A^-$ ) in groundwaters move through internal and external fluid pathways to complete the cell circuit. b, Cross-section from the Whaleback Mine at Newman, Western Australia, with a hypothetical reconstruction of the now eroded extension of the structure, illustrating the proposed electrochemical model at an advanced stage of deep iron ore formation during the Proterozoic. Fluid pathways at depth are provided initially by the fault zone, later extending laterally and vertically, by leaching of BIF.

magnetite usually weathers more slowly than other susceptible components in BIF.

Polarization tests, at pH values 4–9, on electrodes of magnetite indicate that it is an essentially inert electrode. Addition of ferrous ion to the solution produced oxidation reactions in the region of +0.3 V (SHE). With BIF electrodes the response was the same when ferrous ion was added. In the absence of added ferrous ion, however, there was still a slight indication of reaction at +0.3 V (SHE) which led us to investigate this phenomenon in a different cell.

The cell used was designed to allow current and voltage levels to be varied while surface reactions could be observed under the microscope; its design will be reported in detail elsewhere. We have shown that reactions are controlled not only by the level of conductivity of the specimens, and by the potentials to which they are subjected, but also by the proximity of reactive non-conductive minerals to the conducting bands of magnetite.

A build-up of iridescent coatings of iron oxide on magnetite surfaces is controlled by conduction, as electrically isolated grains of magnetite within the generally conductive zones are relatively unaffected, although build-up of iron oxide eventually becomes general. Silicates and carbonates in close proximity to conductive magnetites are rapidly attacked, and stilpnomelane in particular tends to swell, often to the extent that flakes of the mineral are released into the cell solution. At the same time other parts of the exposed surface become pitted as carbonate grains are dissolved; in some cases corrosion extends beyond the area of the specimen initially exposed in the cell, as solution penetrates along susceptible bands below plastic masking.

Comparable features have been observed in outcrop samples where, for example, certain bands of magnetite, carbonates and silicates may be extensively oxidized or corroded while adjacent bands are relatively fresh.

Supergene alteration of BIF does not necessarily involve oxidation of magnetite. Deep drilling in the vicinity of ore bodies at various sites in the Province has intersected severely altered and friable BIF in which chert has been strongly leached, but in

which magnetite is still fresh. In some cases this altered but unoxidized BIF grades downward into strongly goethitized zones. In the Paraburdoo 4E deposit<sup>7</sup> a high-grade haematite ore lens occurs 200 m down dip below surface ore. The intervening BIF is still fresh in places despite the precambrian age<sup>4</sup> of this ore.

Thus the evidence suggests that the electronic paths will be left relatively intact during deep ore formation, although leaching of other minerals takes place.

Oxidation potentials favourable for reaction (2) will exist along much of the conducting paths, but an essential requirement for deep-seated ore formation in our model is a zone at depth with greater initial porosity and better fluid access than in almost impermeable zones closer to the surface. The 'corrosion cell' is completed by electrolytic conduction through the general groundwater system, connecting the permeable anode with the cathode at the surface. These conditions would be favoured by faulting (Tom Price<sup>8</sup>, Whaleback<sup>9</sup>, Paraburdoo<sup>6</sup>), and by some structural situations involving damming by intrusives (Paraburdoo<sup>6</sup>) or cross-folding<sup>10</sup>. A hypothetical situation based on Whaleback is shown in Fig. 1b.

The geometry of the systems makes it difficult to test realistically the feasibility of the model in terms of rates of ore formation. A simple approach is to assume the anode and cathode to be of the same area and to regard the BIF conductor as a column of cross-section 1 m<sup>2</sup> and an appropriate length, say 400 m. Such a column will contain ~400 tonnes Fe, about one-third of it as iron (II). If a similar amount of iron (II) is introduced during ore formation, the total amount to be oxidized from iron (II) to iron (III) is about 265 tonnes. Using 4.5 Ωm as the resistivity, 0.7 V as the potential difference, and assuming the conducting path constant at 400 m, the current will be  $0.39 \times 10^{-3}$  A and the time to oxidize all of the iron (II)  $3.7 \times 10^7$  yr. In the actual situation, we envisage that the current from a very large exposed cathode (that is the BIF outcrop), will be concentrated on a much smaller permeable zone at depth, thus increasing the current density and therefore the oxidation

rate at the anode. Even so, the calculated current density, though smaller by at least an order of magnitude than that observed in the slow corrosion of resistant alloys, such as stainless steel<sup>11</sup>, is sufficient to form an ore body in reasonable geological time.

The natural BIF corrosion cell contrasts strongly, in terms of the extent of the cathode and the size of the conductor, with the situation described for Kambalda nickel ores<sup>3</sup>, in which relatively small bodies of conducting sulphides are surrounded by non-conducting country rock. A second major difference is that, whereas the conducting nickel-iron sulphides are oxidized at the anode, in the BIF it is primarily ferrous iron from the interlayered non-conducting carbonates and silicates that is oxidized as a result of the anodic reaction. This was demonstrated in the corrosion cell experiments described above.

Although the iron (II) content of the magnetite is included above in the calculation of the required current density the oxidation of magnetite, *per se*, is not considered to be essential to the first stage of ore-forming process, and will indeed inhibit it unless the oxidation forms conducting maghaemite, for which there is some evidence<sup>5</sup>. Ultimately much of the magnetite will be converted to haematite by a slow solid-state process, or to goethite by hydration<sup>5</sup>. Initial permeability to groundwater is essential, and this will be extended to an enlarged porous zone as attack on carbonates and silicates proceeds. Reactions (1), (2) and (3) will persist as long as there is magnetite and a conducting path to the surface, and diffusion along gradients of  $a_{Fe}^{2+}$  and pH will extend the effective anodic zone. Chert is a major component of these rocks and its removal, an essential part of the ore-forming process, will be facilitated by increased permeability. This leaching is governed by silica activity in ground waters, which is independent of *Eh* and, within normal levels, of pH.

The evidence that some iron has been added to the ore from external sources<sup>5</sup> requires that the deep groundwater which transported it was anoxic. If an electrochemical mechanism were not responsible for precipitating this iron, one would need to invoke a confluence with oxygenated water from the surface which, at the depth of 2,400 m at Krivoyrog or >400 m in the Hamersley Province, would call for remarkable hydrological regimes. James *et al.*<sup>11</sup> invoked oxygenated deep artesian water during extremely arid conditions, but they pointed out that the best ore development seemed to occur in the zones most likely to remain stagnant in their model, suggesting that some other process was operating.

Finally, we stress that the electrochemical model we have proposed is an attempt to explain the more deep-seated ore bodies, and we do not doubt that many ore bodies have resulted from the penetration by oxygen-bearing surface water and, with seasonally fluctuating water tables, from processes akin to lateritization<sup>6,13</sup>. These processes are to some extent electrochemical. Many such ore bodies in the Hamersley Iron Province are closely related to the Tertiary erosion surface, and some indeed form a capping<sup>7-9</sup> on the deeper ore bodies. This capping probably represents the final stage in which downward progression of surface enrichment and erosion meets the upward extension of the deep-seated processes.

## A new date for the Taupo eruption, New Zealand

C. J. N. Wilson\*, N. N. Ambraseys†, J. Bradley‡ & G. P. L. Walker§

\* Geology Department and †Civil Engineering Department, Imperial College, London SW7 2BP, UK

‡ East Asian History of Science Library, 16 Brooklands Avenue, Cambridge CB2 2BB, UK

§ Geology Department, University of Auckland, Private Bag, Auckland, New Zealand

**The Taupo eruption was a complex volcanic event that represents the most recent activity at the Taupo Volcanic Centre<sup>1</sup> in the North Island of New Zealand. The average<sup>2</sup> of many radiocarbon ages dates the eruption at ~AD 130. The records of ancient China and Rome refer to events in ~AD 186 of the type which follow a major volcanic eruption, and we present here reasons for considering that these events were due to the Taupo eruption, and that the true date of the eruption is ~AD 186.**

The products of the Taupo eruption are rhyolitic and are dispersed over a large part of the North Island<sup>2</sup>. They consist of an initial plinian pumice-fall deposit (the Hatepe Pumice)<sup>2</sup>, two phreatoplinian<sup>3</sup> ashes (the Putty Ash and Rotongaio Ash)<sup>4</sup> which are separated by an erosion break, the 'ultraplinian' Taupo pumice-fall deposit<sup>5</sup> and finally the non-welded Taupo ignimbrite<sup>6-8</sup>.

Preliminary calculations indicate an erupted volume of >60 km<sup>3</sup> (20-25 km<sup>3</sup> dense-rock equivalent), of which 24 km<sup>3</sup> and >30 km<sup>3</sup> are represented by the Taupo ultraplinian pumice-fall deposit and Taupo ignimbrite respectively. This eruption was thus comparable in magnitude to the ~1500 BC eruption of Santorini<sup>9</sup>.

Recent studies on the Taupo ultraplinian pumice-fall deposit<sup>5</sup> and Taupo ignimbrite<sup>6-8</sup> show that they were the most violent eruptions of their type yet documented. The eruption column which produced the ultraplinian pumice-fall deposit was of great power and height. Inserting the estimated dense-rock equivalent eruption rate<sup>5</sup> of 10<sup>6</sup> m<sup>3</sup> s<sup>-1</sup> in published eruption-column models<sup>10,11</sup> yields estimates of the eruption column height of not less than 50 km. Estimates of the initial grain-size population for the ultraplinian eruption column indicate the presence of an unusually large proportion of fine-grained material (ref. 5; and G.P.L.W. and C.J.N.W., unpublished data). It is evident that large quantities of fine ash must have been injected into the stratosphere and incorporated into the upper-atmosphere circulation.

Numerous <sup>14</sup>C ages were determined before 1962<sup>12</sup> on carbonized vegetation enclosed in the eruption products, and 22 selected values were averaged by Healy<sup>2</sup> to yield the eruption-date estimate of 1,819 ± 17 yr BP, or AD 131. Note, however, that the individual <sup>14</sup>C ages used to compile this average have much larger standard deviations (usually at least ±50 yr) than the average date itself.

A search within the ancient Chinese and Roman histories revealed the occurrence of phenomena similar to those that followed the 1883 eruption of Krakatoa<sup>13</sup>.

In the Chinese literature, it is recorded that:

"During the reign of (the emperor) Ling Ti (AD 168-189) several times the Sun rose in the east red as blood and lacking light, only when it had risen to an elevation of more than two *zhàng* was there any brightness. When it set in the west, at two *zhàng* above the horizon it was similarly red. . . . Also during this period, several times when the Moon rose and set and was two to three *zhàng* above the horizon, all was red as blood."<sup>14</sup>

‡ Present address: 18 Juniper Lane, Amherst, Massachusetts 01002.

A *zhàng* is approximately equal to 12° (ref. 15).

In the Roman literature, two sources refer to unusual appearances of the sky in, or just before, AD 186.

"Before the war of the deserter (autumn 186), the heavens were ablaze."<sup>16</sup>

"Stars were seen all the day long and that some did stretch in length hanging as it were in the midst of the ayre which was a token of a cloud not kindled but drouen together for it seemed kindled in the night, in the day when it was far off it vanished away."<sup>17</sup>

These descriptions are reminiscent of the effects observed to follow the 1883 Krakatoa eruption and particularly the characteristics of the Krakatoa dust haze (ref. 13, pp. 223–225) in higher latitudes. The appearance and description of the haze as being too thin to produce blue or green-coloured suns, as having a rippled or striated appearance and only being visible around dawn and dusk (recall "... in the day when it was far off it vanished away") and the accompanying glow effects, seem to correspond closely with the above descriptions.

These records of phenomena resulting from a major eruption in or just before AD 186 and the absence of records of similar effects between then and the Vesuvius eruption of AD 79, suggest that the records do indeed refer to the Taupo eruption and therefore that the true date of this eruption is ~AD 186.

Two problems arise. First, what chance is there of material erupted at Taupo (38° 50' S) being able to spread across the tropics and into the Northern Hemisphere in quantities sufficient to cause noticeable effects? Although Northern Hemisphere temperature records<sup>18,19</sup> show a minor change at the time of the 1886 Tarawera (New Zealand) eruption<sup>20</sup>, this is not considered as significant enough to indicate that material can cross the tropics. Lamb<sup>21,22</sup> has stated (for example, ref. 22, p. 416) that: "... volcanic dust originating in high latitudes hardly spreads in significant quantities beyond about latitude 30° in the hemisphere of origin; though small quantities may reach any part of the Earth, it effectively covers only latitudes 30°–90° in the hemisphere of origin...". Note that Lamb was referring to the dispersal of volcanic ash in the lower stratosphere, from the tropopause up to ~25–27 km. On the other hand, data quoted earlier indicate that the Taupo ultraplinian eruption-column penetrated the upper stratosphere and reached the mesosphere. Fine ash injected at such levels would take times of the order of months to years to fall to lower levels<sup>21</sup> and in the meantime be subject to the high level (>30 km) drift which crosses the equatorial regions between the hemispheres (see ref. 21, p. 455). Thus the finest ash, injected at the greatest heights, could spread from New Zealand to the Northern Hemisphere with little difficulty.

This is in accord with the above descriptions; the absence of blue or green suns or moons suggests that the causative particles were <5 µm across<sup>13,22</sup>. Also, the nature of the Chinese description implies that the glow effects appeared gradually and lasted for some time; other reports of sunset-glow effects found by one of us (J.B.) in the Chinese literature (almost certainly caused by middle or northern-latitude eruptions) are generally closely dated (often to the nearest month) as to when they first appear.

The second problem is that an AD 186 eruption date lies just outside three standard deviations of the average of the <sup>14</sup>C dates (1,819 ± 17 yr BP). However, since the dates were published, much work has been done on the corrections required to convert <sup>14</sup>C ages to true ages derived by dendrochronology. Michael and Ralph<sup>23</sup> have obtained <sup>14</sup>C dates of AD 118 and AD 148 on samples with true dates of AD 150 and AD 197 respectively, while Suess<sup>24</sup> has obtained a <sup>14</sup>C date of AD 119 on material of true date AD 185. (All these <sup>14</sup>C dates were calculated using the 5,568-yr half life, for valid comparison with the New Zealand dates; reported standard deviations are ±40, 44 and 45 yr respectively.) The difference between the proposed AD 186 true and AD 131 <sup>14</sup>C eruption dates is, therefore, very close to that between true and <sup>14</sup>C dates obtained on samples from the same true-age period.

One slight possibility is that these atmospheric phenomena resulted from the eruption which produced the north lobe of the White River Tephra in Alaska<sup>25</sup>, <sup>14</sup>C dated at about 1,890 yr BP (average of 11 determinations<sup>25</sup>). Applying the true date to <sup>14</sup>C date corrections as above<sup>23,24</sup> suggests that in this case, the <sup>14</sup>C date of ~AD 60 is close to the true age, and that the White River eruption did not produce the effects seen in or just before AD 186 here ascribed to the Taupo eruption.

We conclude that the Taupo eruption, previously dated by <sup>14</sup>C methods at AD 131, actually occurred in ~AD 186. The scale of the eruption, its violence, and the wide dispersal of the resulting air-fall deposits suggest that enough fine dust escaped into the upper-atmospheric circulation to reach the Northern Hemisphere and produce the optical effects observed in China and Europe.

Whilst this new date is only a proposal, we hope that we have demonstrated the potential of using historical records in dating and characterizing the distant effects of large volcanic eruptions.

Confirmation of this new date for the Taupo eruption might be sought in Antarctic or Arctic ice cores. Alternatively, a New Zealand dendrochronology time scale could be constructed and correlated with the timber enclosed abundantly in the Taupo ignimbrite.

We thank Dr J. Needham for assistance and Drs J. Westgate and L. Wilson for helpful comments. C.J.N.W. is an NERC research student and G.P.L.W. a Captain James Cook Research Fellow of the Royal Society of New Zealand. J.B. thanks the East Asian History of Science Library for facilities.

## Output rate of magma from active central volcanoes

G. Wadge

Lunar and Planetary Institute, 3303 NASA Road One, Houston, Texas 77058

For part of their historic records, nine of the most active volcanoes on Earth have each erupted magma at a nearly constant rate. These output rates are very similar and range from 0.69 to 0.26 m<sup>3</sup> s<sup>-1</sup>. The volcanoes discussed here—Kilauea, Mauna Loa, Fuego, Santiaquito, Nyamuragira, Hekla, Piton de la Fournaise, Vesuvius and Etna—represent almost the whole spectrum of plate tectonic settings of volcanism. A common mechanism of buoyantly rising magma-filled cracks in the upper crust may contribute to the observed restricted range of the rates of output.

**Table 1** Historic output rates of magma from selected volcanoes

| Volcano               | Plate tectonic setting | Product                             | Period    | Volume ( $\times 10^6 \text{ m}^3$ ) | No. of eruptions | Output rate ( $\text{m}^3 \text{ s}^{-1}$ ) | Refs   |
|-----------------------|------------------------|-------------------------------------|-----------|--------------------------------------|------------------|---|--------|
| Kilauea               | Intraoceanic           | Tholeiitic basalt                   | 1823–1975 | 3,323                                | 54               | 0.69  | 1–3    |
| Mauna Loa             | Intraoceanic           | Tholeiitic basalt                   | 1823–1975 | 3,158                                | 37               | 0.66  | 1, 4   |
| Fuego                 | Subduction             | High $\text{Al}_2\text{O}_3$ basalt | 1932–1979 | 700                                  | 28               | 0.5   | 5      |
| Santiaguito           | Subduction             | Dacite                              | 1922–1972 | 658                                  | 14               | 0.42  | 6      |
| Piton de la Fournaise | Intraoceanic           | Hawaiite                            | 1931–1974 | 529                                  | 21               | 0.39  | 7      |
| Nyamuragira           | Intracontinental       | Leucite basanite                    | 1901–1971 | 838                                  | 12               | 0.38  | 8      |
| Hekla                 | Spreading ridge        | Basaltic andesite<br>Dacite         | 1693–1970 | 2,731                                | 4                | 0.31  | 9      |
| Vesuvius              | Intracontinental?      | Leucite basanite                    | 1760–1944 | 1,660                                | 20               | 0.29  | 10, 11 |
| Etna                  | Subduction             | Hawaiite                            | 1759–1974 | 1,746                                | 31               | 0.26  | 12     |

The volumes of lava and tephra have been corrected to magmatic volumes at liquidus temperatures. The bulk densities of the lava flows are not accurately known, but the corrections are small. A factor of 0.85 was applied to the lavas of Kilauea<sup>14</sup> and also to Mauna Loa and Hekla. A factor of 0.94 based on my unpublished data for lavas of Etna, was applied to the lavas of Etna, Nyamuragira and Santiaguito. For the dacitic tephra of Hekla a correction factor of 0.20 was used<sup>33</sup>, and one of 0.45 was used for the basaltic tephra of Etna and Nyamuragira. The number of eruptions is a general guide, and in the cases of Etna and Vesuvius refers only to the major lava-forming eruptions. For Hekla with its long repose periods, the time used to calculate the output rates starts after the 1693 eruption and ends after the 1970 eruption. The output rate for Piton de la Fournaise as originally published<sup>7</sup> was too great by a factor of 10.

The rates at which magmas have been erupted at these nine volcanoes have been calculated from estimates of the volumes of their historic products<sup>1–12</sup> (Table 1). These volcanoes were chosen because of the availability of data of similar quality. Each is a major central volcano of considerable age ( $>10,000$  yr) which has been active for much of the recent historic past. Using volumetric data to calculate output rates can only be justified for those volcanoes whose cumulative volume curves are approximately linear (Fig. 1). The volcanoes of Table 1 not shown in Fig. 1 also satisfy this criterion. It has been suggested that the combined output rate for Mauna Loa and Kilauea is constant<sup>13</sup>. Because of the uncertainties in the data for the summit, caldera-filling lavas for both these volcanoes, complete cumulative volume curves are not shown in Fig. 1. However, judged solely on the historic flank eruptions of Mauna Loa which account for ~80% of the total for this volcano, the curve is linear. Hence the output rate is considered valid for Mauna Loa and probably also for Kilauea.

The nine volcanoes of Table 1 show a very restricted range of output rates which cannot be considered an artefact of a single observer's bias despite the levels of uncertainty (several tens of per cent) in the volume estimates. This small sample cannot be considered representative of volcanism in general in that these volcanoes have been unusually active and unusually well studied. Nevertheless, there is no ready explanation for such a common output rate and its significance may extend beyond the individual volcanoes reported here. Departures from linearity in the cumulative volume curves of Vesuvius and Etna are apparent in Fig. 1 and have been previously discussed in terms of the evolution of intravolcanic magma chambers and magma supply<sup>11,12</sup>. An episodic character to the recurrence of activity at Fuego, represented here in its most recent history has been detected<sup>5</sup>. Thus a constant output rate may represent a state of equilibrium that can only be maintained for a limited period of time.

Not all magmas that rise beneath volcanoes reach the surface. Some may freeze in intrusions<sup>14</sup>, or become involved in crystal fractionation and host rock digestion<sup>15</sup>. Kilauea is the only volcano for which there is geological and geophysical evidence that magma is supplied at a constant rate which is greater than the subaerial output rate<sup>14</sup>. This supply rate of  $3.6 \text{ m}^3 \text{ s}^{-1}$  is about five times the observed historic output rate, the balance being taken up mainly by submarine effusion and dyke intrusion. This has been applicable for the past 30 yr (refs 14, 16, 17). Supply rates for magma entering the other volcanoes can only be guessed at. The evidence from Kilauea suggests that constant output rates at each of the nine volcanoes represent a partitioning of ascending magma into a fraction which is erupted and a fraction which remains below the surface. Thus it is conceivable that each volcano has a constant supply rate that is larger than its

output rate but falling within a similarly restricted range of values.

Buoyant rise of magma in cracks is a mechanism which may explain a constant supply rate to these volcanoes. A magma-filled crack experiences a net force of  $(\rho - \rho')gV$ , where  $\rho$  is the density of the rock,  $\rho'$  is the density of the magma,  $g$  is the value of gravity and  $V$  is the volume of the crack<sup>18</sup>. The densities of the magmas considered here range from  $\sim 2,600 \text{ kg m}^{-3}$  (olivine tholeiite) to  $2,300 \text{ kg m}^{-3}$  (dacite) at liquidus temperatures and atmospheric pressure. Up to 5 kbar pressure the increase in densities is small ( $<100 \text{ kg m}^{-3}$ )<sup>19,20</sup>. The density contrast for basalts will be smaller than for andesites and dacites, and for an average crustal density of  $2,670 \text{ kg m}^{-3}$  a factor of five covers the range of density contrasts  $(\rho - \rho')$ , though this is sensitive to the local rock density.  $V$  is restricted by the lithospheric stress field; the greater stress at the base closes the crack as its tip migrates upwards. A free crack has a stable vertical length,  $L$ , given by

$$L \leq 2 \left[ \frac{K_c}{\sqrt{\pi} g (\rho - \rho')} \right]^{2/3}$$

where  $K_c$  is the fracture toughness of the rock<sup>21</sup>. For a density contrast of  $100 \text{ kg m}^{-3}$  in rocks of fracture toughness of  $100 \text{ MN m}^{-2/3}$   $L$  is  $\sim 3,000 \text{ m}$ . The width of the crack is variable but an average width of 10 m is geologically realistic and this would give a typical volume for a disk-shaped crack of about  $70 \times 10^6 \text{ m}^3$  and a net buoyancy of 70 GN.

This crack volume is of the same order of magnitude as the individual eruption volumes for most of the volcanoes in Table 1. Such cracks would need to arrive at the volcano every 6–7 yr to account for the observed output rates, more frequently if there is subsurface loss of magma. Magma-filled cracks, therefore, are of appropriate size and the ascending magma has a buoyancy controlled by parameters which may vary within sufficiently narrow limits to produce the observed similarity of output rates of volcanoes from very different tectonic settings.

If the magma is to remain liquid during conduction of heat to the cold walls it must have a minimum average ascent velocity. The calculations of Marsh for andesite-filled cracks<sup>22</sup> give a velocity of  $10^{-3} \text{ m s}^{-1}$ . A recent quantitative model of magma ascent at Kilauea<sup>23</sup> involves magma rising along cracks at velocities between  $10^{-2}$  and  $10^{-1} \text{ m s}^{-1}$ . The petrology and geochemistry of the products of the October 1974 eruption of Fuego have been interpreted<sup>24</sup> in terms of a magma-filled crack of volume  $100 \times 10^6 \text{ m}^3$  rising at an average velocity of  $10^{-3} \text{ m s}^{-1}$  for the last 8 km to the surface. These figures indicate the minimum average velocities though the real motion will be incremental<sup>25</sup>. In addition, the viscosity of the liquid has an important limiting effect on crack velocity<sup>26</sup>. The limiting effect will be much stronger for highly viscous siliceous magmas than for that for less viscous basaltic magmas. Although this problem

cannot be considered here it has an important bearing on volcanic magma supply.

Most of the world's mature, subaerial central volcanoes have been considerably less active in historical times than those discussed here. Many have erupted no magma for hundreds of years. This may mean that magma is not being supplied to these volcanoes because it is being intercepted by a large crustal reservoir or because magma is not entering the crust at all. In a review of ash flow eruptions of all sizes, Smith<sup>27</sup> proposes a tentative correlation between ejecta volume and the time taken to produce this material. This rate is  $0.03 \text{ m}^3 \text{ s}^{-1}$  ( $10^{-3} \text{ km}^3 \text{ yr}^{-1}$ ), which is about 1/10th of the output rates presented here. There have been several published estimates of the volumetric productivity of large sections of several volcanic arcs situated above subduction zones. These estimates are usually expressed in  $\text{km}^3 \text{ Myr}^{-1} \text{ km}^{-1}$  of arc, and range from 5 to  $30 \text{ km}^3 \text{ Myr}^{-1} \text{ km}^{-1}$  (refs 28–32) for various periods of the Quaternary. If an average of 50 km of arc is allocated to each volcanic centre, each volcano produces  $\sim 250\text{--}1,500 \text{ km}^3 \text{ Myr}^{-1}$  or  $0.008\text{--}0.05 \text{ m}^3 \text{ s}^{-1}$ . This is between 2 and 10% of the historic

output rates shown by the Table 1 volcanoes near subduction zones. These two comparisons suggest that if the output rates reported here are more generally applicable to arc volcanoes when they are in an active state, then their corresponding periods of inactivity must last about 10–50 times longer.

I thank W. I. Rose Jr, S. Self and C. A. Wood for reviews of an earlier manuscript. Part of this work was done while I was a visiting scientist at the Lunar and Planetary Institute which is operated by the Universities Space Research Association under Contract NSR-09-051-001 with NASA.

**Fig. 1** Cumulative volume curves compiled from the historic records of five volcanoes. The curve for Mauna Loa is for flank eruptions during 1843–1978. The curves for Nyamuragira and Hekla are for the periods used in Table 1, whilst the linear portions of the curves for Etna and Vesuvius used in Table 1 are bracketed by the dashed lines. The solid curves for Etna<sup>12</sup> are for 1535–1974, and for Vesuvius<sup>10,11</sup>, 1630–1979. Note that the abscissa scale for Mauna Loa and Nyamuragira is different from that for the other three volcanoes.

## Calcium-carbonate-phosphate surface complex in calcareous systems

Yoram Avnimelech\*

Faculty of Agricultural Engineering, Technion,  
Israel Institute of Technology, Haifa, Israel

The interactions between soluble orthophosphates and lime ( $\text{CaCO}_3$ ) have been extensively studied because of the frequent occurrence of soil systems rich in  $\text{CaCO}_3$  and the dominant effect of calcium carbonate on phosphate solubility. Several investigators have suggested that in these systems chemically defined calcium phosphate species are precipitated. Cole and Olsen<sup>1</sup> found that the solubility of phosphate in calcareous soils seems to be controlled by a di-calcium phosphate (DCP) solid phase, although the solubility product inferred ( $2.89 \times 10^{-9}$ ) is significantly less than that measured<sup>2</sup> for DCP ( $2 \times 10^{-7}$ ). Similar results have been reported for the interaction between fish-pond sediments and the aqueous phase<sup>3</sup>. On the other hand, Stum and Leckie<sup>4</sup> have suggested that the solubility of phosphate in calcareous systems may be controlled by the chemisorption of phosphate on  $\text{CaCO}_3$  particles, with the formation of amorphous calcium phosphates<sup>5</sup> or of surface complexes.<sup>4</sup> We now describe experiments which argue for the formation of a surface complex of calcium-carbonate-phosphate with well defined chemical composition.

\* Present address: The USDA-SEA Water Quality Management Laboratory, Durant, Oklahoma 74701.

The experiments consisted of adding phosphate to suspensions of analytical grade  $\text{CaCO}_3$ . In the first series,  $\text{K}_2\text{HPO}_4$  solutions, buffered with KOH to pH 8.4, were added drop by drop. Later, phosphate-enriched anion exchange resin (Dowex 2) contained in a fine nylon cloth was used to maintain a slow supply of phosphorus. The suspensions were shaken for periods of 3–25 days. Systems planned to provide data on material balance were tightly sealed to avoid gains or losses of  $\text{CO}_2$ . The samples were filtered and measurements made of: pH with a glass electrode, calcium with atomic adsorption using nitrous oxide flame, phosphate colorimetrically<sup>6</sup> and carbonates by titration<sup>7</sup>. Ionic distribution in the solution was computed using constants for the dissociation of the orthophosphoric and carbonic acids and stability constants for the ionic pairs  $\text{CaHPO}_4$ ,  $\text{CaH}_2\text{PO}_4^+$  (ref. 2),  $\text{CaCO}_3^\circ$ ,  $\text{CaHCO}_3^-$  (ref. 8) and  $\text{CaOH}^+$  (ref. 9).

The material balance of components in the solution during the reaction of potassium phosphate with calcium carbonate in a sealed system over 25 days is given in Table 1. A transfer of a component from the solution to the solid is defined as a negative change whereas dissolution, or desorption, is defined as a positive change. The balance for hydrogen is made on its free ionic species,  $\text{H}_3\text{O}^+$ , as well as on other species containing protons, such as  $\text{HCO}_3^-$  and  $\text{HPO}_4^{2-}$ .

Calcium is lost from the solution after the addition of phosphorus, but the losses become smaller with the increased phosphorus concentration and are not related to the changes in phosphorus concentration. The changes in total carbonate concentration follows the same pattern, but in the range of high phosphorus losses (above  $\sim 3 \times 10^{-4} \text{ mol P l}^{-1}$ ), carbonate is released from the solid into the solution. The transfer of hydrogen from the solution to the solid is linearly related to that of phosphorous. The linear regression is:

$$\Delta\text{H} = 0.59 + 2.11 \Delta\text{P}, \quad r = 0.965 \quad (1)$$

and the best estimate of  $\Delta\text{H}$  as a function  $\Delta\text{P}$  is

$$\Delta\text{H} = 2.625 \Delta\text{P} \quad (2)$$

If the reaction occurring in the system tested here was the precipitation of any known calcium phosphate, the ratio of precipitated calcium to that of phosphorus should be constant and in the range between 1.67 to 1.0, the stoichiometric Ca/P ratios in hydroxyapatite and DCP, respectively, that is

$$\frac{\text{Ca precipitated}}{\text{P precipitated}} = \text{constant}; \quad 1.0 \leq \text{constant} \leq 1.67 \quad (3)$$

The precipitated calcium includes that disappearing from the original solution, as well as calcium that is possibly added into the solution, by a dissolution of  $\text{CaCO}_3$ . Any gain of soluble calcium is associated with an identical gain in carbonate. Thus, calcium precipitated with phosphate is given by

$$\text{Ca (P-p.p.t.d.)} = -(\Delta\text{Ca} + \Delta\text{CO}_3) \quad (4)$$

where  $\Delta\text{Ca}$  and  $\Delta\text{CO}_3$  are the changes in total calcium and carbonate respectively, from the time of phosphorus addition until the end of the experiment.

The ratio of precipitated Ca to precipitated P, averaged for

the data presented in Table 1, is 0.620. This ratio is not within that defined by equation (3) and thus is not consistent with the hypothesis that a known calcium phosphate shall have precipitated.

Equations (5)–(10) describe six possible reactions between  $\text{CaCO}_3$  and phosphoric acid, together with the resultant  $\Delta\text{H}/\Delta\text{P}$  ratios.

Reactions (5)–(7), leading to the formation of distinct calcium phosphates (DCP, octa-calcium phosphate or hydroxyapatite) do not lead to an appreciable binding of hydrogen to the solid phase. Reactions (8)–(10), describing the formation of calcium-carbonate-phosphates, lead to an equivalent binding of phosphate and hydrogen ions to the solid phase. The necessary  $\Delta\text{H}/\Delta\text{P}$  ratio is 3.

The linear relation found between the transfer of hydrogen and phosphorus from the solution to the solid (equation (2)), yields a  $\Delta\text{H}/\Delta\text{P}$  ratio of 2.6. This ratio tends to decrease, however, with the increase in phosphate concentration. This trend, and the fact that the experimental  $\Delta\text{H}/\Delta\text{P}$  ratio is lower than that demanded by equations (8)–(10), is probably because some fraction of the phosphate had reacted with calcium according to reactions (5)–(7).

These considerations and results suggest that the reaction between  $\text{CaCO}_3$  and orthophosphate can be formulated as

According to equation (11), and the potential diagram suggested by MacGregor and Brown<sup>10</sup>, the chemical potentials of the components participating in reactions (8)–(10) can be related through equation (12).

$$n\mu\text{CaCO}_3 + \mu\text{H}_3\text{PO}_4 = F^\circ \text{ solid} \quad (12)$$

or

$$n \ln(\text{CaCO}_3) + \ln(\text{H}_3\text{PO}_4) = \text{constant} \quad (13)$$

**Table 1** Material balance in  $\text{CaCO}_3$  suspensions enriched with phosphate

| Changes in solution composition ( $\text{mol l}^{-1}$ ) |                                    |                                   |                                   |                                   |

**Fig. 1**  $\text{H}_3\text{PO}_4$  potential as a function of  $\text{CaCO}_3$  potential in  $\text{CaCO}_3$  suspensions equilibrated with phosphorus adsorbed on anion exchange resin. ●, Experiment (1), 5 g  $\text{CaCO}_3$  per 200 ml; ×, experiment (2), 5 g  $\text{CaCO}_3$  per 200 ml; ○, experiment (3), 1 g  $\text{CaCO}_3$  per 200 ml.

where the values in parentheses represent the activity of the given components.

According to equation (13), the logarithm of  $\text{CaCO}_3$  activity plotted against that of  $\text{H}_3\text{PO}_4$  should yield a straight line, the slope of which is equal to  $n$ , the stoichiometric ratio of  $\text{CaCO}_3$  to  $\text{H}_3\text{PO}_4$ .

Calcium carbonate suspensions were equilibrated during three days with phosphated anion exchange resin. The experimentally derived data are presented, in a potential diagram form, in Fig. 1. The points follow a straight line defined by

$$\log (\text{H}_3\text{PO}_4) = 64.23 - 3.11 \log (\text{CaCO}_3); \quad r = -0.951 \quad (14)$$

This line is in accordance with equation (13), and the slope suggests that the reaction occurring and controlling the system is that described by equation (10).

The formation of a surface compound  $\text{Ca}_3(\text{HCO}_3)_3\text{PO}_4$  agrees with the crystal structure of calcite or aragonite. In both crystals, three calcium ions are located on the surface for each unit cell<sup>11</sup>.

The linear relation between the  $\text{CaCO}_3$  and  $\text{H}_3\text{PO}_4$  potentials seems to disagree with the reported relationship between the chemical potentials of  $\text{Ca}(\text{OH})_2$  and  $\text{H}_3\text{PO}_4$  (refs 1, 3), but the present experimental data also yield a straight line when  $\log \text{H}_3\text{PO}_4$  is plotted against  $\log \text{Ca}(\text{OH})_2$ . This ambiguity stems from the fact that in any system at which  $\text{H}_2\text{CO}_3$  potential is constant (systems in equilibrium with the atmosphere),  $\text{Ca}(\text{OH})_2$  potential is related to  $\text{CaCO}_3$  potential. Thus, in any system controlled by equation (14), and maintaining a constant  $p\text{CO}_2$ ,

the phosphoric acid potential will show an apparent dependence on  $\text{Ca}(\text{OH})_2$  potential.

The existence of the surface compound,  $\text{Ca}_3(\text{HCO}_3)_3\text{PO}_4$ , also has an effect on the solubility of  $\text{CaCO}_3$ . The activity of  $\text{CaCO}_3$  in the solution is equivalent to the ionic product  $(\text{Ca}) \cdot (\text{CO}_3)$ . The data in Fig. 1 clearly indicate that this product is a function of the phosphoric acid potential and not a constant value. When the phosphoric acid potential is high, the ionic product drops significantly below the solubility product of calcite ( $pK = 8.31$  (ref. 8)).

## Plant-controlled supratidal anhydrite from Al-Khiran, Kuwait

A. Gunatilaka, A. Saleh & A. Al-Temeemi

Department of Geology, Kuwait University, Kuwait

We report here that in the supratidal zone of the Al-Khiran sabkha, diagenetic anhydrite occurs exclusively in association with the living halophyte *Halocnemum strobilaceum* (Pallas) M.B. This anhydrite has a hair cream-like consistency and the bulk of it has formed as pseudomorphs after gypsum crystals. On the death of the plant at the end of its life cycle, the anhydrite is hydrated back to gypsum. This two-way transformation results in a series of characteristic textures, whose preservation could be due to the comparative 'youth' of the sabkha, which is in the very earliest stages of evaporite diagenesis.

A Recent carbonate–algal stromatolite–evaporite cycle <2-m thick and covering an area >60 km<sup>2</sup> occurs in the Al-Khiran area of Kuwait. The depositional area is in contact with the open waters of the Arabian Gulf by means of two large tidal channels (khors) which provide the main hydraulic energy input into the system. The physiography and sedimentary pattern of the region is shown in Fig. 1.

The supratidal zone proper or sabkha is marked by the occurrence of the halophyte *Halocnemum strobilaceum* (Pall.) M.B., which covers an area 1–3 km wide and extends continuously for ~15 km. Here the groundwater table is no more than 50–70 cm from the surface. Tidal flooding of this zone has not been observed, but probably occurs when strong winds and high tides coincide. The summer temperatures on the sabkha surface can vary between 42 and 55 °C (April to October) and winter temperatures from 20 to 35 °C (November to March). Evaporation rates are very high and rainfall (1979–80) can be up to 12 cm yr<sup>-1</sup>. Relative humidity values are generally <50%. The tidal range in the khors is >2 m at the mouth and <30 cm at the extremities. In all cases, the evaporite minerals present were confirmed by X-ray diffraction studies.

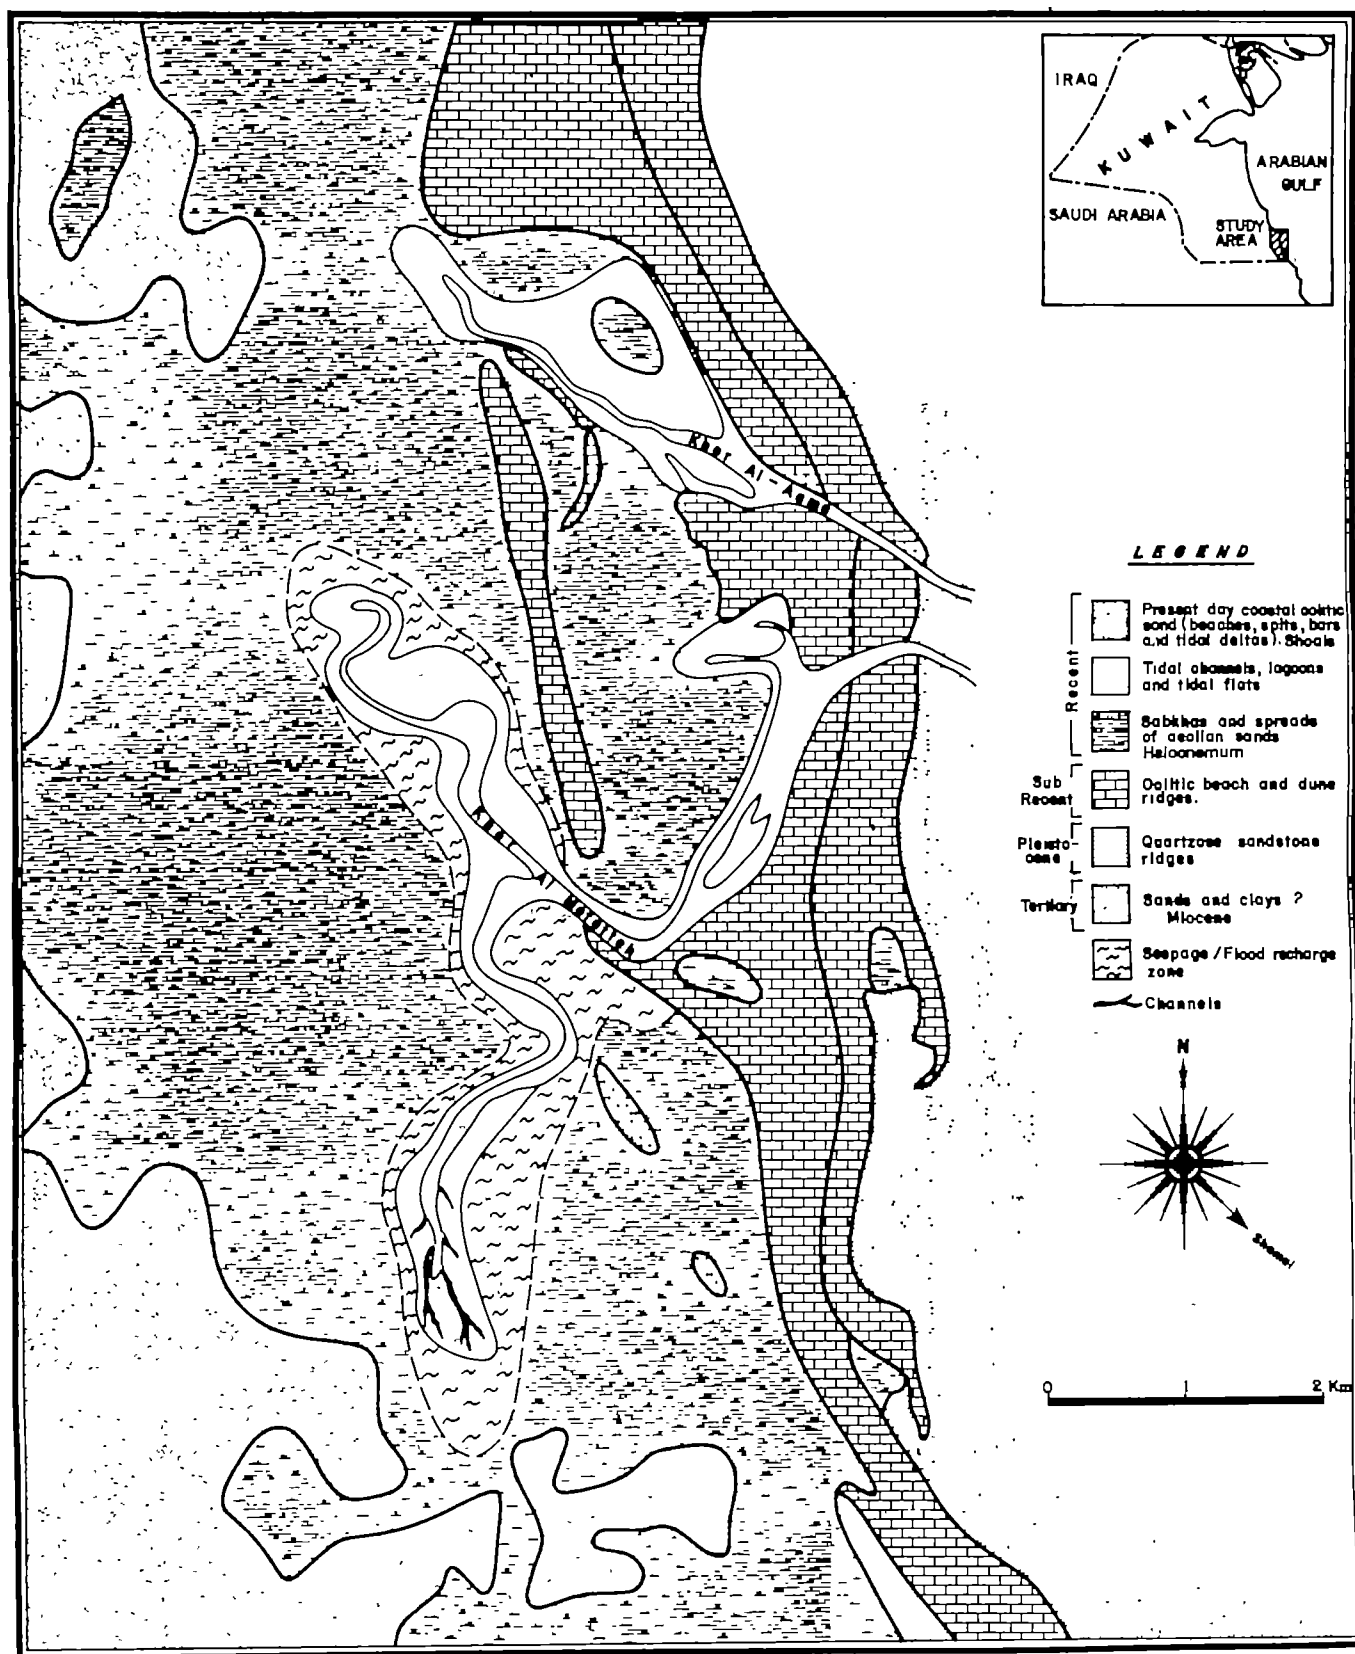

Fig. 1 Physiography and sedimentary pattern of the Al-Khiran area.

The first occurrence of anhydrite in the supratidal zone coincides with the appearance of the *Halocnemum* plant. It occurs as white patches exclusively around the plants, forming small elevated humps above the general surface (Fig. 2). It was also observed that the anhydrite is formed only around the mature, fully grown plants, in layers 3–12-cm thick with the characteristic consistency of hair cream (not the 'cottage cheese'

consistency as in Abu Dhabi). The stratigraphic relationships in a 30-cm core taken through the plant has the features shown in Table 1.

The anhydrite first begins to form as single nodules in the gypsum mush, a few centimetres below the sabkha surface, around the roots. Several of these nodules eventually coalesce to form irregular laminae, which in turn form the anhydrite layers

**Table 1** Stratigraphic features of a *Halocnemum* plant taken from the Al-Khiran area of Kuwait

| Depth (cm) | Dominant minerals   |
|------------|---|
| 0–1        | Wind-blown material, aragonite, gypsum, anhydrite, dolomite, halite |
| 1–7        | Anhydrite nodules or layers, some gypsum + trace dolomite           |
| 7–9        | Cemented gypsum crust   |
| 9–10       | Gypsum + some anhydrite   |
| 10–19      | Gypsum mush + minor aragonite + dolomite                            |
| 19–25      | Aragonite + gypsum + some dolomite                                  |
| >25        | Aragonite mud   |

around the plant. The continued growth of the gypsum below this zone contorts the layering, eventually resulting in structures resembling enterolithic veins. In section, the anhydrite layer looks like a 'diapir' with a *Halocnemum* bush in the middle. In fact, the surface expression of the anhydrite is directly related to the extent of the root network at depth. The diameter of these patches vary from 20 to 70 cm.

In thin section, the anhydrite occurs as perfect pseudomorphs after diskoid gypsum crystals of variable size (Fig. 3). The pseudomorphs are not formed by the infilling of diskoid voids left by the dissolution of gypsum crystals as suggested by Butler<sup>1</sup>. The gypsum–anhydrite transformation is a direct dehydration *in situ*, and the bulk of the nodules in the sabkha formed originally as pseudomorphs after gypsum within the host sediment. The evaporite minerals developing in the sabkha include aragonite, gypsum, bassanite, anhydrite, halite, protodolomite, celestite and magnesite. Detailed microscopic and X-ray diffraction studies indicate that the anhydrite and protodolomite are formed through replacement reactions between gypsum and aragonite and coexisting sabkha brines within the sediment. Note that in all the textures studied, the anhydrite had a gypsum precursor. There is no evidence for any orthochemical precipitation of anhydrite as a primary mineral in this sabkha<sup>2,3</sup>.

We believe that a brine concentration of 7–8 × SSW (standard seawater of chlorinity 19.377‰) necessary to form the anhydrite, is achieved by combining the effects of evapotranspiration activity of the *Halocnemum*, the osmotic activity of the roots and the cemented gypsum layer below, which regulates the capillary flow of the water. The mass dehydration around the plant results in a series of evaporitic textures caused mainly by the creation of new voids. The gypsum–anhydrite transformation results in a volume reduction<sup>4</sup> of ~36%.

Many dead plants occur within the supratidal zone. When associated with such plants, the anhydrite changes to a dirty grey or buff colour and the area around the plant becomes hum-

mocky. Vuggy features tend to develop and the entire surface starts breaking up, by which time the thixotropic consistency of the anhydrite has changed to one resembling moist and hardened flour. Microscopically this change is reflected in the rehydration of the anhydrite back to gypsum. The original pseudomorphs are destroyed and are replaced by a new series of hydration textures which are quite unlike that of any reported before from sabkhas. Around the dead plants optimal physico-chemical conditions probably do not prevail to concentrate the brines sufficiently (7–8 × SSW) and keep the system within the metastable field of anhydrite.

In thin section, the first change observed is the splaying open of the anhydrite pseudomorphs, brought about by the increase in volume due to rehydration (a 66% volume increase)<sup>4</sup>. Most pseudomorphs are flattened along their *c*-axes and the best developed cleavages are normal to the long axis of a crystal. The crystal is split along the latter cleavages, resulting in small, discrete sub-crystals or cleavage laths of anhydrite having rectangular cross-sections. These are very soon hydrated to gypsum laths pseudomorphic after the anhydrite cleavage laths. This is alabastrine secondary gypsum because of its microcrystalline–cryptocrystalline nature. Clumps or aggregates of these laths always show undulating extinction shadows when the microscope stage is rotated. The range of new textures developed vary from collapsing nodules of anhydrite/secondary gypsum laths (both of which originated in diskoid anhydrite

**Fig. 3** Photomicrograph of anhydrite pseudomorph after gypsum from the supratidal *Halocnemum* zone. Scale bar, 0.1 mm.

pseudomorphs) to 'granoblastic and preferred orientation textures'<sup>5</sup>. Perhaps the most interesting intermediate stage is the generation of a nested or 'augen'-like texture, where a nodule of anhydrite pseudomorphs or a single anhydrite grain is surrounded by gypsum laths showing a distinct lineation and indicating some flowage (Fig. 4). Compaction settling and pore water pressures causing liquefaction in poorly draining sediments are believed to cause lineation fabrics in anhydrite laminites<sup>6</sup>. If so, the inter- and intra-nodular permeability characteristics within the sediments could play a crucial part in their genesis. The compact and hardened nature of the alabastrine gypsum is probably due to the decrease in the void space between the laths, caused by the volume increase during hydration.

The hydration mechanism is thought to be dominantly one of dissolution of anhydrite followed by reprecipitation as gypsum<sup>7</sup>. However, there is no evidence that this occurs in Al-Khiran. Finally, when camel herds trek across the *Halocnemum* zone, their footprints soon convert the alabastrine gypsum pseudomorphic laths back into anhydrite, but with an aphanitic, felted texture<sup>5</sup>. Although the latter is probably a result of sustained compaction, followed by slippage or gliding of the breaking microcrystalline laths, the exact mechanisms involved are

**Fig. 2** Occurrence of hair-cream anhydrite (white patches) around the *Halocnemum* plants.

Fig. 4 Photomicrograph showing aligned fabric of gypsum laths. Note the nested anhydrite crystals. Scale bar, 500  $\mu\text{m}$ .

obscure. The main changes observed are:

Diskoid primary gypsum  $\rightarrow$   
 anhydrite pseudomorphs  $\rightarrow$   
 anhydrite cleavage laths  $\rightarrow$   
 alabastrine secondary gypsum pseudomorphic laths  $\rightarrow$   
 felted-aphanitic anhydrite.

Supratidal anhydrite associated with plants is of interest and there is experimental evidence regarding anhydrite precipitation in the presence of organic matter<sup>8</sup>. The occurrence of anhydrite in Al-Khiran is obviously controlled by the physiological requirements of the halophyte. Whether this difference with the widespread Trucial Coast anhydrite is due to the different climatic regimes (less rainfall and no vegetative cover in Abu Dhabi) is not clear. The absence of anhydrite in the North African sabkhas is probably due to the large influx of continental groundwaters and the semi-arid climatic regime<sup>9,10</sup>. We have also observed incipient anhydrite formation in a very restricted intertidal channel area, where a reducing organic-rich (algal/bacterial) laminated sediment is forming. Isolated gypsum grains altering to anhydrite were observed 4–5 cm below the intertidal surface in scattered locations. Though quantitatively insignificant, this, albeit rare, occurrence indicates that Perthuisot's oxidizing environment theory for the Arabian Gulf anhydrites needs to be treated with caution<sup>11</sup>. The Al-Khiran chemical data are yet incomplete to assess the general applicability of this idea.

The present conclusions made regarding the genesis of this unique occurrence of anhydrite in an Arabian Gulf sabkha are tentative because studies are continuing to relate the evaporite mineral assemblages to the chemistry of the coexisting brines within each zone. Many of the features reported here are either absent or not well represented in the classic Trucial Coast sabkhas. The comparatively youthful Al-Khiran sabkhas are still in the 'early' stages of a first cycle of carbonate sedimentation. Here, the intertidal algal mat does not extend inland below the present sabkha surface, and typical chicken-wire anhydrite is absent.

We thank Dr Graham Evans for visiting the study area and making critical comments on many aspects of this study.

## Particulate organic carbon flux in the oceans—surface productivity and oxygen utilization

Erwin Suess

School of Oceanography, Oregon State University, Corvallis, Oregon 97331

Organic detritus passing from the sea surface through the water column to the sea floor controls nutrient regeneration, fuels benthic life and affects burial of organic carbon in the sediment record<sup>1–3</sup>. Particle trap systems have enabled the first quantification of this important process. The results suggest that the dominant mechanism of vertical transport is by rapid settling of rare large particles, most likely of faecal pellets or marine snow of the order of  $>200 \mu\text{m}$  in diameter, whereas the more frequent small particles have an insignificant role in vertical mass flux<sup>4–6</sup>. The ultimate source of organic detritus is biological production in surface waters of the oceans. I determine here an empirical relationship that predicts organic carbon flux at any depth in the oceans below the base of the euphotic zone as a function of the mean net primary production rate at the surface and depth-dependent consumption. Such a relationship aids in estimating rates of decay of organic matter in the water column, benthic and water column respiration of oxygen in the deep sea and burial of organic carbon in the sediment record.

The relationship is based on flux data compiled from particle traps installed throughout the world's oceans<sup>7–19</sup> by many investigators and from annual mean organic carbon production rates of the respective surface waters<sup>20–29</sup> (Table 1). In a few cases biological production rates were determined at the time of installing the sediment trap<sup>12,16</sup>, the remaining data were compiled from other sources, often using annual mean rates from the general area of investigation. The predicted flux may overestimate the proportion of surface production intercepted at any given depth, when traps were installed during times of peak productivity (which was mostly the case) but then were normalized to lower mean annual production rates. Accordingly, equation (1) gives an upper limit of the net vertical carbon flux, if the production is known:

$$C_{\text{flux}(z)} = \frac{C_{\text{prod}}}{0.0238z + 0.212};$$

$$n = 33, \quad r^2 = 0.79, \quad z \geq 50 \quad (1)$$

$C_{\text{prod}}$  is the primary production rate of carbon at the surface,  $C_{\text{flux}}$  is the organic carbon flux at depth measured by the sediment traps, both in units of  $(\text{g m}^{-2} \text{ yr}^{-1})$ ,  $z$  ( $\geq 50$ ) is the water depth (m) at which the traps were moored,  $n$  is the number of observations, and  $r^2$  the coefficient of correlation. Only flux data from below the euphotic zone ( $>50 \text{ m}$ ) are used in defining equation (1). This limitation also causes the non-zero intercept for  $b = 0.212$ . Moreover carbon fluxes in shallow waters, as in the western Baltic Sea<sup>12,13</sup> and along cross-shelf transects of the Peru coastal upwelling regime<sup>16–18</sup>, are consistently less than predicted by extrapolating equation (1) to such depths (Fig. 1). These low yields are probably due to non-vertical motions of particles caused by advection, horizontal currents and locomotion of live plankton, thus exporting particulate matter from the site of sediment trap deployments.

Effects of  $\pm 15\%$  uncertainty in primary production estimates are also shown in Fig. 1. This uncertainty is of the same magnitude as the variations and ranges of repeated flux measurements obtained using several traps at the same location. For example, particle flux measurements below the California Current<sup>10</sup> were repeated within the same season whereas the data from the Peru coastal upwelling system<sup>17,18</sup> are averaged.

over several seasons, as indicated in Table 1. The collection and closure efficiency of certain trap designs, the problems of *in situ* decay of non-poisoned collectors, horizontal and resuspended flux probably contribute even more significantly to the scatter of the data<sup>30,31</sup>.

However large the present uncertainties may be for the relationship of vertical fluxes of particulate carbon in the oceans, they have interesting implications. First, if depth can be adequately transformed into time, the slope of equation (1) implies some sort of rate constant. Actual measurements of large particle size spectra with depth are not available. For small particles ( $d < 100 \mu\text{m}$ ) many theoretical models and empirical distribution patterns have been presented which suggested that particle populations get smaller in diameter with increasing depth<sup>4,32</sup>. The decrease in particle diameter with depth is thought to be a function of various chemical dissolution or oxidation processes<sup>33-35</sup>. Thus one would expect a gradual decrease in particle settling rates with depth. However, recent investigations suggest that biological repacking by successive feeding actually produces larger particles at the expense of smaller ones and that settling rates are extremely rapid<sup>36</sup>. A relationship of carbon-flux to surface-production from which minimum sinking rates can be inferred was recently also observed by Deuser and Ross<sup>14</sup> who showed that seasonality in surface production is reflected in like changes of the carbon flux in the deep Sargasso Sea. The coupling between production at the surface and deep flux—here at a depth of 3,200 m—within a period of a month or less, requires sinking rates of particles in excess of  $100 \text{ m day}^{-1}$ . Also Shanks and Trent<sup>6</sup> measured sinking rates of  $\sim 50\text{--}100 \text{ m day}^{-1}$  for other large aggregates (marine snow) primarily involved in vertical mass transfer.

As a first approximation, then, depth and residence time may be linearly related and for simplicity a settling velocity of  $w_s = 100 \text{ m day}^{-1}$  may be assumed in transforming depth ( $z$ ) of equation (1) into time. This then enables the definition of an

apparent rate constant for organic carbon decomposition from equation (2):

$$\frac{1}{C_{\text{flux}(z)}} - 0.212 = 2.38t \quad (2)$$

$$\frac{C_{\text{prod}}}{C_{\text{prod}}}$$

where  $C_{\text{prod}}$  = production at  $t = 0$ , and the constant  $k = 2.38$ , (that is  $z(0.0238)$ ), has the dimension  $\text{day}^{-1}$  and the properties of a second-order rate constant. This is inferred because equation (2) is analogous to the expression for second-order rates in chemical kinetics:  $1/C_t - 1/C_0 = kt$ . In testing experimental data to ascertain second-order rate kinetics,  $1/C_t$  plotted against  $t$  should yield a straight line relationship whose slope is equal to the rate constant  $k$  and the intercept equal to  $1/C_0$ . Accordingly, a fit for the carbon flux data in relation to depth ( $z$ ), to settling velocity ( $w_s$ ) and to primary production  $C_{\text{prod}}$  defines the equation above.

As a second implication, the extrapolation of the predicted carbon flux from equation (1) to the interception with the sea floor at any site yields the net carbon sedimentation before burial. This is independent of the actual rate laws and mechanisms that control organic matter consumption at depth or the variation in sinking rates of particulate matter. Net carbon sedimentation is an important parameter because it gives the upper limits of organic carbon accumulation in the sediment column. The preserved rate of burial can only be smaller than this flux. The magnitude of continued consumption of organic matter from the time it arrives at the sediment surface to the

Fig. 1 Organic carbon fluxes with depth in the water column normalized to mean annual primary production rates at the sites of sediment trap deployment. The undulating line indicates the base of the euphotic zone; the horizontal error bars reflect variations in mean annual productivity as well as in replicate flux measurements during the same season or over several seasons; vertical error bars are depth ranges of several sediment trap deployments and uncertainties in the exact depth location. The data points by Rowe (1980) represent selected averages of 2–5 single sites at  $\sim 10 \text{ m}$  above the bottom, where resuspension was assumed to be minimal.

† Ref. 38.

time it is effectively removed from decomposition through burial is related to benthic respiration. In many cases the burial rate of organic carbon can be independently determined from linear bulk sedimentation rates, sediment densities, porosities and organic carbon contents. Consequently, the benthic respiration is the difference between the net vertical flux as predicted by equation (1) and the burial rate. The burial rate of organic matter, in turn, seems to be primarily controlled by the linear rate of sedimentation, as discussed elsewhere<sup>37</sup>. Results in Table 2 at two stations from the coastal upwelling regime off Peru illustrate how to estimate benthic respiration from vertical carbon flux minus carbon burial rate. The carbon utilization rates and the inferred bottom oxygen demand are well within the ranges reported from other coastal upwelling areas. Based on benthic production and faunal analyses, Christensen and

Packard<sup>38</sup> estimated benthic oxygen utilization rates at water depths ranging from 20 to 200 m for coastal upwelling areas off north-west Africa and Baja California to be between 93 and 345 (l m<sup>-2</sup> yr<sup>-1</sup>). Also, oxygen utilization rates of 60-550 (l m<sup>-2</sup> yr<sup>-1</sup>), with strong seasonal fluctuations, are reported from the first direct measurements of O<sub>2</sub>-distribution profiles *in situ* and from incubation experiments of near-shore anoxic sediments from the western Baltic Sea<sup>39,40</sup>.

The most far-reaching, yet tentative implication, is coupling oxygen consumption in the water column to the observed changes in vertical flux of particulate organic carbon. If for every 106 mol organic carbon consumed, 138 mol oxygen are utilized<sup>41</sup> and if the residence time of the particles within a parcel of seawater can be ascertained, rates of oxygen utilization at any depth can be predicted. Again for simplicity, assuming a mean sinking rate for particles  $w_s = 100 \text{ m day}^{-1}$  yields the distribution of the total cumulative oxygen utilization with depth as:

$$\Delta O_2 = C_{\text{prod}}(6.66 \times 10^{-5}) \left[ 1 - \frac{1}{0.0238(z) + 0.212} \right] \quad (3)$$

where the constant  $6.66 \times 10^{-5}$  converts carbon consumption to oxygen utilization in units of (ml l<sup>-1</sup> day<sup>-1</sup>); that is  $\frac{1}{365} \text{ g C-org}$

m<sup>-2</sup> day<sup>-1</sup> utilizes  $2.43 \times \frac{1}{100} \text{ m}^3$  when assuming settling velocity

of particles  $w_s = 100 \text{ m day}^{-1}$ ; therefore,  $\frac{2.43}{365} \times 10^{-5} \times 10^3 =$

$6.66 \times 10^{-5} \text{ ml l}^{-1} \text{ day}^{-1}$ . The proportion of organic carbon

consumed is given by the expression  $1 - \frac{1}{0.0238(z) + 0.212}$  and

again,  $z$  is limited to depths  $\geq 50 \text{ m}$ . To illustrate the usefulness of equation (3), vertical distribution profiles of oxygen consumption rates are generated for a water-column profile where the input of oxidizable particulate organic matter from the euphotic zone is between 100 and 500 g C m<sup>-2</sup> yr<sup>-1</sup> and the vertical mass transfer is assumed to be primarily through large particles at sinking rates of  $100 \text{ m day}^{-1}$ . Comparable oxygen consumption rates in water-column profiles deduced from electron transport activities, bacterial utilization rates and respirometer measurements are in general agreement with these predicted values, although ETS O<sub>2</sub>-consumption rates appear higher by an order of magnitude at greater water depths (Fig. 2)<sup>42-45</sup>. Equation (3) also assumes O<sub>2</sub>-consumption to be only by the utilization of particulate organic matter, whereas actually, dissolved organic carbon is also utilized<sup>46</sup>.

The oxygen distribution resulting from the predicted consumption rates of equation (3) largely follows that of the classical circulation model by Wyrki<sup>47</sup>, the basic difference being that his model utilizes an exponential oxygen consumption term with depth following first-order rate kinetics, that is  $C_t = C_0 e^{-kz}$ , whereas the carbon flux measurements presented here are better approximated by a second-order fit. The only way that the carbon flux data would follow a first-order rate expression is in the case of accelerated settling of particles; that is, if sinking rates were actually to increase with depth in the water column.

These early results from particle traps apparently tie together successfully processes of organic carbon cycling in the oceans that previously have been treated separately by marine biologists, chemists and sedimentologists. Sizes and shapes of particles involved in vertical mass flux and seasonally adjusted surface productivity and deep carbon fluxes hold the key to understanding fully organic carbon cycling in the ocean and related oxygen and nutrient distributions.

This work was supported by the NSF and the Office of Naval Research through grants OCE-77-20376 and N00014-79-C-0004, Project NRO83-1026 to Oregon State University. I thank J. Dymond, P. D. Komar and R. Pytkowicz for helpful discussions.

I dedicate this work to Richard Cobler, an inspiring student of oceanography and a friend.

**Fig. 2** Vertical distribution of oxygen consumption rates in the ocean derived from changes of particulate carbon fluxes. The profiles are generated from equation (3) for mean primary productivities of between 100 and 500 g C-org m<sup>-2</sup> yr<sup>-1</sup>, respectively. Vertical transfer of particles is at constant sinking rate of  $100 \text{ m day}^{-1}$ . Maximum potential oxygen consumption rates are shown for comparison from electron transport activities (□) and the corresponding estimated actual oxygen utilization (■). □, Oxygen consumption from bacterial utilization rates. The data points represent a composite profile from the eastern Pacific Ocean<sup>42-45</sup>; note scale changes.

## Concomitant photoautotrophic growth and nitrogenase activity by cyanobacterium *Plectonema boryanum* in continuous culture

H. W. Pearson &amp; R. Howley

Department of Botany, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK

Since the discovery that nitrogenase activity will develop in cultures of *Plectonema boryanum* in microaerobic conditions<sup>1</sup>, this phenomenon has been demonstrated in numerous other non-heterocystous cyanobacteria<sup>2-4</sup>. However, there is controversy as to whether such organisms are capable of sustained concomitant nitrogenase activity and photoautotrophic growth<sup>2,4,5</sup>. An exogenous carbohydrate source (fructose) and strongly reducing conditions (produced by bubbling liquid cultures with a N<sub>2</sub>/CO<sub>2</sub>/H<sub>2</sub>S gas mixture) have been deemed necessary for continuous logarithmic green growth and nitrogenase activity by batch cultures of *Plectonema boryanum* in the light. We report here sustained exponential growth and nitrogenase activity by *P. boryanum* in continuous culture gassed with nitrogen in the absence of further chemical reducing agents and exogenous carbohydrate sources.

An aerobic continuous culture of *P. boryanum* was established in a chemostat with nitrate (1 mM) in the medium as the combined-nitrogen source and light intensity the factor controlling the rate of growth. General conditions for culture were as described in Fig. 1 legend, except that the fermenter was gassed with air (instead of nitrogen) and the rate of dilution was faster ( $D = 0.072 \text{ h}^{-1}$  rather than  $0.048 \text{ h}^{-1}$ ). With the population in steady state in these carbon-limited growth conditions, the ratio of phycobiliprotein to chlorophyll *a* (an indication of the nitrogen status of the cells<sup>1,5</sup>) was 1.030, the cell density 0.115 absorbance units and the cell doubling time 9.6 h. After 10 d of steady-state growth, nitrogen starvation was imposed by omitting nitrate from the inflowing medium. The culture turned yellow within ~36 h, growth virtually stopped (as evidenced by a rapid rate of washout) and the ratio of phycobiliprotein to chlorophyll *a* dropped from 1.030 to 0.903. Thus the higher ratio was obtained when nitrogen was not limiting growth, whereas the lower ratio occurred in conditions of nitrogen starvation.

We used the basic conditions established for aerobic photoautotrophic growth of *P. boryanum* in continuous culture; cells previously grown with nitrate were inoculated into combined-nitrogen-free medium under an atmosphere of nitrogen and grown in the fermenter for 3-4 d in batch culture. During this period nitrogenase activity commenced and cell density increased. The fermenter was then switched to the continuous mode by pumping combined-nitrogen-free medium through the culture while bubbling it with oxygen-free nitrogen gas (inorganic carbon was supplied as bicarbonate in the inflowing medium). The culture stabilized to give a steady-state cell density after approximately 48 h. Figure 1 shows that simultaneous photosynthesis, nitrogenase activity and photoautotrophic exponential growth were sustained by *P. boryanum* in this microaerobic continuous culture. The filaments showed no visible signs of yellowing in spite of a ratio of phycobiliprotein to chlorophyll *a* of 51.56% of the value recorded for the aerobic cultures grown with nitrate.

Our nitrogenase activity (1.00 nmol C<sub>2</sub>H<sub>4</sub> per mg protein per min) for *P. boryanum* in continuous culture was substantially less than that quoted for batch cultures grown in a sulphide-stat amended with fructose<sup>5</sup>. Nevertheless it provided sufficient fixed nitrogen to support a higher specific growth rate ( $\mu = 0.048 \text{ h}^{-1}$ ), equivalent to a cell doubling time of 14.4 h compared to ~24 h reported by Rogerson<sup>5</sup>. The growth pattern described here could be maintained almost indefinitely.

We next investigated the effect of adding sulphide at levels known to suppress oxygenic photosynthesis. To establish the range of inhibitory concentrations, we incubated samples of the culture with various concentrations of sulphide: photosynthesis was severely inhibited above 300  $\mu\text{M}$ . We therefore incorporated sulphide into the inflowing medium and it reached a concentration of 300  $\mu\text{M}$  in the fermenter after 20 h, at which time the photosynthetic rate of *P. boryanum* had dropped to 14% of its initial steady-state value. In spite of this severe reduction in carbon fixation, nitrogenase activity was stimulated sevenfold and the specific growth rate of the culture steadily increased for 48 h before falling again in response to carbon starvation. Thus, while previously maintaining a high rate of growth in nitrogen-fixing photoautotrophic conditions, *P. boryanum* accumulated sufficient photosynthetically derived carbon to support a prolonged period of increased growth in the light, in conditions favouring nitrogen fixation but inhibiting photosynthesis. The stimulation of nitrogenase by the added sulphide was reflected in the increased production of phycobiliprotein relative to chlorophyll *a* to a value higher than during growth with nitrate.

Although sulphide reduced the dissolved oxygen concentration in the medium to  $31.7 \pm 1.7 \mu\text{M}$ , the studies of Stewart and Lex<sup>1</sup> suggest that this alone could not account for all the increase in nitrogenase activity. In microaerobic conditions the controlling factor seems to be intracellular accumulation of photosynthetically produced oxygen, rather than the diffusion of

**Fig. 1** Nitrogen-fixing photoautotrophic growth of *Plectonema boryanum* (UTEX 594) in chemostat continuous culture. The growth medium was a modified ASM recipe<sup>11</sup>, free of combined-nitrogen but with  $\text{NaHCO}_3$  (12 mM final concentration) added as the source of carbon dioxide. The culture (1,000-cm<sup>3</sup> volume) had a dilution rate of 48 cm<sup>3</sup> h<sup>-1</sup> and was gassed with oxygen-free nitrogen (100 cm<sup>3</sup> min<sup>-1</sup>) and stirred continuously. The pH of the medium in the fermenter was adjusted to 8.9. When required, sulphide was pumped into the fermenter (the arrow denotes the start of this procedure) from a separate reservoir of  $\text{Na}_2\text{S}$  solution maintained in anoxic conditions. The dilution rate of the culture was kept constant. Illumination by 125-W white fluorescent tubes provided a light intensity at the fermenter surface of 97.5  $\mu\text{E m}^{-2} \text{s}^{-1}$  photosynthetically active radiation (6,000 lux) and the temperature was maintained at  $29 \pm 1^\circ\text{C}$ . Dissolved oxygen ( $\blacktriangle$ ) was determined using a Clark-type oxygen electrode housed in a small chamber remote from the main fermenter body into which a sample of the culture could be diverted when measurements were to be made. This prevented poisoning of the electrode by prolonged contact with the medium when it contained sulphide. The optical density of the culture ( $\bullet$ ) was estimated spectrophotometrically at 540 nm (1 cm pathlength) and the phycobiliprotein to chlorophyll *a* ratio ( $\blacksquare$ ) calculated from measurements at 625 and 678 nm respectively. Nitrogenase activity ( $\square$ ) was estimated by the acetylene reduction technique in a gas phase of 10%  $\text{C}_2\text{H}_2$  balance nitrogen, as described previously<sup>11</sup> but by means of a Perkin Elmer FII gas chromatograph. Sulphide concentration ( $\triangle$ ) was determined by the methylene blue photometric method<sup>12</sup>. Rates of carbon fixation ( $\circ$ ) were measured as before<sup>7</sup> except that  $\text{NaH}^{14}\text{CO}_3$  was added directly to samples from the fermenter.

oxygen into the cells from the culture medium. Sulphide thus allowed increased expression of nitrogenase activity by penetrating the cells<sup>7</sup> and reducing the intracellular oxygen tension by two possible mechanisms: (1) the chemical reduction of photosynthetically produced oxygen, as was likely in Rogerson's work<sup>5</sup>, because 5–8  $\mu\text{M}$  sulphide at pH 7.8 does not appreciably inhibit oxygenic photosynthesis in *Plectonema* (Fig. 2), and (2) the direct suppression of photosynthetic oxygen production as in our experiments (Fig. 1).

Nagatani and Haselkorn<sup>8</sup> have suggested that the shortage of reductant is the major factor limiting induced nitrogenase activity in microaerobic cultures of *Plectonema*. If so the increased rate of nitrogenase activity in the presence of sulphide might be due not just to the elimination of molecular oxygen *in vivo* but also to the supply of reductant directly to the nitrogenase system by sulphide. This could explain the high rates of acetylene reduction we observed with sulphide present, even

when the specific growth rate had started to decline rapidly after day 12 (Fig. 1) due to carbon starvation. In such conditions supplies of reductant and ATP from respiration are likely to be severely restricted. But because sulphide, at the concentrations used, inhibits photosynthetic electron transport through photosystem II while photosystem I is unaffected, cyclic photophosphorylation could provide the ATP in the light and sulphide could donate the bulk of the electrons directly to the nitrogenase system.

Because nitrogenase activity due to stimulation by sulphide leads to the apparent 'luxury' production of phycobiliprotein, as a nitrogenous reserve compound, it seems unwise to draw conclusions about the functioning of photosystem II based solely on a high phycobiliprotein to chlorophyll *a* ratio especially as sulphide inhibited virtually all photosynthetic activity in our culture. Nevertheless, our results point to the potential for renewed photosystem II activity should inhibitory sulphide concentrations prove transitory, as in many natural environments such as temperate salt marshes, mud flats and sand dune slacks.

Our data show that in microaerobic continuous culture *P. boryanum* can sustain a high rate of exponential growth based solely on its own photosynthetic and nitrogen-fixing capacities. The simultaneous and stable rates of photosynthesis and nitrogenase activity do not support the idea of temporal separation of these processes as a mechanism for protecting the nitrogenase from inactivation by oxygen<sup>9</sup>.

Sulphide probably stimulates nitrogenase activity by eliminating intracellular photosynthetically produced oxygen, but sulphide ions may also provide reductant to the nitrogenase system. Oxygenic photosynthesis was markedly more sensitive to sulphide poisoning than was nitrogenase activity but *P. boryanum* can exploit this situation by using stored photosynthate as shown here, or by switching to photoheterotrophic growth if suitable exogenous substrates are available<sup>10</sup>.

Given the apparent absence of a special cellular mechanism to permit microaerobic nitrogen-fixing photoautotrophic growth by *P. boryanum*, it is likely that other non-heterocystous cyanobacteria with oxygen-sensitive nitrogenase systems *in vivo* could grow similarly.

R.H. was supported by a NERC studentship.

**Fig. 2** Carbon fixation by *P. boryanum* at different sulphide concentrations (pH 7.8). Values are expressed as a percentage of the sulphide-free controls and are the means of triplicate samples. Experimental procedure was similar to that described previously<sup>7</sup>.

## The robustness of natural systems

Alan Roberts\* & Ken Tregonning†

\*Physics Department, Monash University, Clayton, Victoria 3168, Australia

†Research Branch, Forests Commission, 1 MacArthur Place, Melbourne, Victoria 3000, Australia

Although the relation between complexity and stability in natural systems has been widely investigated<sup>1</sup>, a number of other basic questions remain largely unstudied. For example: can we find fundamental properties which identify a persistent natural system? Are these properties due to the process by which such a system emerges? Is this process—natural selection—also responsible for that robustness which is so generally superior to that of an artificial system? This peculiar robustness of a natural system can show itself in a wide variety of ways; the resistance to shock and efficient nutrient conservation of a climax community<sup>2</sup>, for example, or the physical stability of proteinoid microparticles<sup>3</sup>. Can we find other system properties which help to explain this robustness—properties which transcend the particular type of system under consideration? Such a 'universal' set of requirements is indeed suggested by the results reported here. In the model studied, the survivor systems turn out to be composed, at every subsystem level, of subsystems each of which is independently viable. These viable subsystems are nested, overlapping, strongly connected and extraordinarily numerous, implying a 'defence in depth' for the main system against major collapse. Some important conclusions can be made about these model systems: first, an artificial system comparable in its size and complexity could hardly have this robust structure built into it; second, if grossly damaged, a natural system will usually be reduced to one of its viable subsystems. The components eliminated could, of course, include ones vital to human interests. Full restoration of the damage would not generally be practicable.

We have not followed the procedure usually applied to examining related questions, which has focused on the system's stability. This mathematical concept assumes that an attainable equilibrium is already present, and examines how the system reacts to subsequent departures from it, but clearly one should first look for factors which determine whether an equilibrium will be attained at all. (This is obviously true when local equilibrium about an equilibrium point is studied, but also applies to more complicated cases such as limit cycle behaviour, where a stable cycle loop cannot exist unless an attainable equilibrium point lies within it.) This is all the more advisable because, in a whole range of important cases, the existence of an attainable equilibrium effectively guarantees stability anyway<sup>4</sup>.

Here, then, we look for properties which distinguish a system with an attainable equilibrium. More specifically, we consider interacting variables  $N_1, N_2, \dots$ , varying with time, which can take only positive values. (Examples may include the 'populations' of animal, plant or chemical species, measured in numbers of individuals or (bio)mass.) Thus a set of mathematically possible equilibrium values  $N_1^*, N_2^*, \dots$  can be attained

only if they are 'feasible'—that is, all  $N_i^* > 0$  (ref. 5). Terms used here are 'species', 'populations' and 'feasible' equilibria.

This approach has a further substantial advantage: the model examined can be a very general one, so that any findings are widely applicable and far less dependent on the minutiae of a particular model specification. We write

$$dN_i/dt = f_i(N_i) [r_i + A_i(N_1, N_2, \dots, N_M)], \quad i = 1 \text{ to } M \quad (1)$$

Here the functions  $A_i$  describe the interactions between and within species; we will see that their form can be left almost completely open. The functions  $f_i$  are likewise left unspecified; they describe the species' reproductive (or decay) behaviour, as do the constants  $r_i$ . We require, however, that  $f_i(0) = 0$ , to exclude spontaneous creation.

In many types of system there are mechanisms by which the species can 'adapt' to each other, so that, over a long enough period of coexistence, the interactions take on a systematic character. However, because it is precisely the conditions for this initial coexistence which interest us, we exclude this possibility by requiring the species to interact randomly. We also exclude any species which, if left in isolation, would increase without limit, by requiring all species to be self-regulated.

The randomness of interaction will generally result in the disintegration of the assemblage as time goes on, with one or more species dying out. When  $M$  is large, only a small fraction of the solutions will survive intact, corresponding to rare configurations of the  $A_i$ . The nature of this survival can be mathematically various (local stability about  $N^*$ , limit cycle, strange attractor—see ref. 1, Ch. 2), and can generally be unravelled only if the  $A_i$  are fully known. However, for its survival to be possible, a system must first have a feasible equilibrium point. Thus, by studying the assemblages described by feasible solutions of equation (1), we are studying all possible candidates for survival as a persistent system.

Because we use numerical methods, definite probability distributions must be chosen. We first rewrite equation (1) formally as

$$dN_i/dt = f_i(N_i) \left[ r_i + \sum_{j=1}^M A_{ij}^* N_j \right] \quad (2)$$

Here the  $A_{ij}^*$  are partial derivatives, and only mild restrictions need be imposed on the interactions  $A_i$  to justify rewriting in this form. (All first partial derivatives must be continuous; the first mean value theorem then gives equation (2), the derivatives being evaluated at a point which depends on the specific form of  $A_i$  but not on  $j$ .)

We now express the randomness of interaction by choosing

$$A_{ij}^* = \pm g (i \neq j), \quad r_i = \pm 1 \quad (3)$$

Here  $g$  is a constant measuring interaction strength; all variates are independent and + or – with equal probability. For self-regulation, we use  $A_{ii}^* = -1$ , all  $i$ .

In our computer studies, we started with a feasible solution for  $M = 25$  variables, generated by the method of 'natural-selective elimination' (ref. 6). We then examined the structure of this solution, proceeding as follows: we selected  $q$  different species at random and eliminated them from the system; the resulting subsystem of  $m = 25 - q$  species was then tested for feasibility. For a given value of  $m$ , 20 such subsystems were sampled (with replacement). This procedure was repeated for all subsystem orders from  $m = 24$  to  $m = 1$ . In all, 100 systems of 25 species each were treated in this way, so that 2,000 subsystems of each order were examined. The value of  $g$  chosen was 0.16, corresponding to a May parameter<sup>7</sup>  $\gamma = (M-1)^{1/2}g = 0.8$  in the 25-species system under study. The number of species with  $r_i < 0$  was 2–11, with a mean of 5.33.

The results are summarized in Table 1. Line *a* shows the mean percentage of  $m$ -species subsystems found to be feasible, for  $m = 1$ –24. (The s.e.m., as estimated from the sample variance, did not exceed 2%.) To appreciate how significantly large these percentages are, they should be compared with those in line *b*. These were derived from a control group of 100 initially

**Table 1** Analysis of the feasibility structure of feasible and unfeasible solutions to equations (2) and (3)

| Subsystem order<br>(no. of species) | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 | 15 | 14 | 13 | 12  | 11 | 10 | 9   | 8   | 7  | 6  | 5  | 4  | 3  | 2  | 1  |
|-------------------------------------|----|----|----|----|----|----|----|----|----|----|----|----|-----|----|----|-----|-----|----|----|----|----|----|----|----|
